In reviewing the second German edition of Dr. Weil's book in 1922 we expressed the hope that an English translation might put within the reach of more students and physicians the sound information contained in its pages. The translation is based on the third edition, and we have nothing but praise for the way in which the work has been carried out. The order of treatment of the subject is original; the ductless glands are not dealt with seriatim, as is the rule in text-books; Dr. Weil studies them according to their effects. He takes the various functions of the body in turn, and discusses the way in which they are modified by the action of the various internal secretions. Finally, the chemical properties of the internal secretions, their inter-relations, and their relations to the central nervous system are discussed. The treatment is logical and stimulating, and the English edition should prove as great a success as other editions have done. Our only word of complaint is concerning the illustrations; these are not nearly so well done as in the original edition of the work. Fig. 12, for instance, shows scarcely anything.

Ophthalmo-Optical Manual.

By William Swaine, B.Sc., Lecturer in Physics, West Ham Municipal Technical College. London: Hatton Press, Ltd. Pp. 152.

This little book, well written, practical, and non-mathematical, should be of much use to the student workers in ophthalmic optics for whom it is intended. Moreover, ophthalmic surgeons will find that it explains some optical phenomena often passed over too lightly in text-books on refraction—e.g., the cylindrical effect produced by the tilting of a lens or by the obliquity of the line of sight when directed through the periphery of a lens, and the varying effectivity of lenses according to their position in front of the eye. About half the book is devoted to purely optical problems, which are strictly within the province of the optician. The other half deals with the optical defects of the human eye, sight-testing, and correction. This part will appeal to the non-medical prescribing optician, and it must be admitted that if the directions found in it are faithfully followed, his results in the majority of adult patients will probably not be unsatisfactory. The optician, however, must necessarily be at a disadvantage compared with the ophthalmic surgeon in dealing with any difficult case of refraction. His subjective tests, however carefully the methods of "fogging" are carried out, are sometimes misleading, and even with the most intelligent patients it may be very difficult to get wholly satisfactory results without either repeated examinations at different times or else the employment of a mydriatic which, by enlarging the pupil and eliminating the accommodation, makes possible an objective test. Mr. Swaine describes the method of retinoscopy, but without a mydriatic he does not pretend that it can attain to the accuracy which he claims for his subjective tests. More important for the non-prescribing optician is the information on frames, mounts, centring of lenses, &c., which will be found here. The subject of bifocal lenses receives notice which is barely adequate to its importance. With this exception the only obvious defects are a statement on the first page that the dazzling sensation experienced by anybody who after having been in the dark for some time enters a well-lit room is due to the time taken by the pupil before it contracts fully to light; and a sentence on page 24 on the numeration of prisms, which is unintelligible. The last ten pages of the manual are devoted to optical tables, which are decidedly useful. They deal, among other things, with the effectivity of lenses at varying distances from the eye, with the prismatic equivalence of different degrees of decentration of lenses, the prismatic effects in near vision of distance centred lenses, and so on.

We have said that this little book is non-mathematical. Those who require mathematical solutions of problems connected with lenses, prisms, and illumination will find what they want from the pen of the same author in almost any number of the *Optician and Scientific Instrument Maker*.

Charts on the Chemical Reactions of the Common Elements.

By John A. Timm, Ph.D., Instructor in Chemistry, Yale University. London: Chapman and Hall. 1924. Pp. 81. 10*s*.

This book consists of series of equations, grouped in a very complicated manner, with no descriptions of the reactions. The author's method is to start the page with the symbol for the element, and, by means of a series of arrows and lines, to give every reaction. The result is a somewhat bewildering collection of lines and symbols, which may be recommended to those who enjoy wrestling with the intricacies of a Bradshaw time-table.

The Plant Alkaloids.

Second edition. By Thomas Anderson Henry, D.Sc., Director, Wellcome Chemical Research Laboratories. London: J. and A. Churchill. 1924. With eight plates. Pp. 456. 28*s*.

In the new edition much of the text has been rewritten and a good deal of new work incorporated without increasing the size of the volume. Less space is now devoted to methods of estimation. On the other hand, more attention has been paid to such information as is available on the correlation of chemical constitution and pharmacological action, a subject upon which it is still impossible to draw any general conclusions. The exact interpretation of the term alkaloid is a matter dependent upon individual opinion, some writers including and others excluding, for example, the group of purin bodies; the present author belongs to the former category. The number of undisputed alkaloids known is already very large, and new additions are continually being made; in these circumstances it is satisfactory to note how some of the alkaloids which figure among those of unknown constitution in the earlier edition appear in the later one among those whose constitution is established; this is notably so in the harmaline and cephalonium series of alkaloids, the last named occurring in the so-called "Mescal buttons." A new feature of the present edition is the inclusion of eight full-page plates, illustrating some of the more important drugs.

Reports and Analytical Records.

"TABLOID" HYPODERMIC INSULIN HYDROCHLORIDE (STERILE).

(Burroughs, Wellcome and Co., Snow Hill Buildings, London, E.C. 1.)

This new "tabloid" preparation of insulin, prepared under conditions formally approved by the Medical Research Council, has been submitted to clinical tests with results that coincide with standard insulin, while the tabloid form ensures sterility, stability, and accuracy of dosage. The product is biologically tested before issue. Each tabloid is equivalent to one average dose of ten clinical units, and when dissolved in 0·5 c.cm. of sterile distilled water is equivalent to an equal volume of standard insulin. The product is supplied in two packings, (1) cartons containing ten tabloids in one tube, and (2) cartons of ten tubes each containing one tabloid.

SOLOID BENEDICT TEST.

(Burroughs, Wellcome and Co.)

This test for sugar in the urine is reputed to be more delicate than Fehling's test. The tabloid outfit consists of a carton containing alkaline citrate and copper sulphate which may be used in one of two ways; in either case the colour change occurs with as little as one per mille of glucose, the change being very pronounced when two per mille or more of glucose is present. The instructions are as follows:—

1. Dissolve one "Soloid" Alkaline Citrate in 30 minims (1·8 c.cm.) of water with the aid of heat. Dissolve one "Soloid" Copper Sulphate in the hot solution and add four drops of urine; mix and boil gently for two minutes. The presence of glucose is indicated by a change in colour and formation of a yellowish to red precipitate.

2. Alternatively, the mixed urine and Benedict Solution may be heated in a boiling water bath for five minutes, allowed to cool, and the colour noted after ten minutes. A change in colour is produced by the urine containing 0·1 per cent. of glucose, and the difference is very decided when 0·2 per cent. of glucose, or more, is present.

The method is intended for qualitative analysis outside the laboratory for patients to whom insulin is being administered and whose urinary sugar content is the deciding factor in treatment. Each carton contains sufficient material for 24 tests.

ALLENBURYS DIET FOR ADULTS.

(Allen and Hanburys, Ltd., 37, Lombard-street, London, E.C. 3.)

This is a partially digested milk and wheaten food which is readily assimilated. While suitable in general for persons of weak digestion it is especially recommended for use by nursing mothers, invalids, convalescents, and the aged. Its preparation entails no trouble; it is simply necessary to add boiling water and stir. The percentage composition of the diet is stated as follows:—

Milk Fat	15·4
Milk and Wheat Protein	15·2
Carbohydrates (Lactose, Soluble Starch, Malto-Dextrin, &c.)	62·9
Mineral Matter	4·3
Moisture	2·2

Calorific Value: 132·3 calories per oz. weight of powder.

This diet is quite distinct from the well-known foods for infants prepared by this firm.

ZEDENO POROUS SHEATH BANDAGE.

(Chas. Zimmermann and Co., 9/10, St. Mary-at-Hill, London, E.C. 3.)

This is described as the Swiss Zedeno dressing for varicose ulcers and is a plastic web bandage which dries at the temperature of the body in about a quarter of an hour after application, forming an even and comfortable sheath for the ulcerated area. It is claimed that by its use relief can be obtained for varicose veins and varicose ulcers without keeping the patient in bed. The composition of the dressing is not stated, but it appears to be an elegant form of Unna's paste and should prove of practical value.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 1, 1924.

SPIRITUAL HEALING.

THE practitioner of so-called orthodox medicine is confronted from time to time with records of "cures" obtained by what are often claimed to be unorthodox methods, and with rumours of still more marvellous results secured, as the exponents of these methods hint, by means of which the ordinary physician has no cognisance. We are told that in matters political the public memory is notoriously short, but in matters medico-therapeutic it is equally true; or, rather, there is an admixture of ignorance with the forgetfulness, for it is surprising how frequently modes of healing that are openly advertised as "new" or "novel" only repeat a technique which is as old as the hills. The undoubted success of not a few varieties of the healing art vaunted as panaceas by enthusiastic disciples, if not always by their supposed originators, offers food for thought and suggests some comments. Without going further back than the last hundred years, the student of the subject can readily recall instances of spiritual healers who have risen to fame and success, and have enjoyed a vogue claimed to be unprecedented, who have, it may be, established schools of devotees, only to fall at length into an equally profound oblivion. The founder of the Mormon religion, JOSEPH SMITH, cast out devils in the name of the LORD, and tried his hand on diseases with no little efficacy, if old records are to be trusted. In fairness it should be said that behind his apparatus of holy oil, consecrated flannels, and the like, SMITH gave shrewd indications that he had at least apprehension, dim though it may have been, of the power of mental suggestion. He recognised his limitations in the cholera epidemic of 1834, and, with a curious combination of religiosity and what the Americans call "horse-sense," held to a theory that healing is a sacerdotal gift, a priestly function, and that without faith no cures are possible. The cult of Dowieism was founded by JOHN DOWIE, of the "Temple of Zion," whose meteor-like rise to heights of notoriety led many of the unthinking to hail him as almost divine, and who published a now utterly forgotten periodical entitled *Leaves of Healing*, filled with wonderful (and preposterous) examples of cures effected "at a distance" through a mystical power of faith of which he was the arch-exponent. More recently still, we hear of a "New Civilisation Church and School," whose teaching, its originator lucidly explains, "is standardising the world and passing all thought into one great universal impulse," and where healing by regeneration through fasting and otherwise holds a prominent place. Again, a little brochure has reached us which heralds the advent in this country of a system of healing "practised with great success for about thirty centuries in Gosainthan, the highest shrine where man holds communion with his Creator, situated 16,800 feet above the sea-level, among the snows of the Himalayas." For a reason that is sufficiently obvious, it is contended that this particular method of *healing* does not "in any way interfere with the Christian *faith*."

If we examine dispassionately such features as these and many other movements of a similar character have had in common, we are met at once with the universal existence of an interrelation between practitioner and subject consisting in sublime self-confidence on the part of the former and eager expectation on the part of the latter. Without this *rapport* no fruitful results can be attained. For the securing of these, further, an atmosphere of emotional preparedness is no less imperative, and the more lush the emotion the more effective is the ceremonial. Of the truth of this statement history provides innumerable instances. If the curious reader will examine the published records of spiritual revivals and camp meetings among any comparatively emotional populace he will find abundant evidence to the purpose. Thus the Rev. SAMUEL J. MOORE published in 1859 a now forgotten little volume entitled "The History and Prominent Characteristics of the Present Revival in Ballymena and its Neighbourhood," in which he scans critically the accompaniments of the movement, and adduces instances both of the appearance of purely hysterical phenomena under the mass-influence of the time and place, and of the "cures" of morbid conditions in the same emotional atmosphere. In an environment of intense sympathetic expectation it is not surprising that resistances are broken down. On a famous occasion, years ago, it may be remembered, the phenomena attributed to the supernormal powers of a celebrated "medium" failed to make their appearance because of the "offensive incredulity" of a young doctor of medicine, happily still with us and known by reputation the world over. Such is the effect of faith, or of unfaith.

Now, when exaggerated if sincere claims are once again being made on behalf of spiritual healing, it is desirable they should be placed in their proper perspective. Of the reality of spiritual emotion there can be no question, but in any discussion of the mechanism of production of the "cures" we are bound in seriousness to ask whether the "spiritual" or the "emotional" factor predominates, whether any distinction is or can be drawn between them, whether the "spiritual" influence accomplishes something beyond the scope of other less pretentious methods. In respect of the last of these our answer must be a direct negative. Cures as "striking," as genuine, and as enduring, are being effected daily in hospitals and consulting-rooms by men who make no claim to tap a wonderful and mystical power outside themselves, who use simple and straightforward means, who adapt themselves to the needs of their patient by explaining technique where this is desirable, or by quiet assurance where the subject does not wish to know, or is intellectually not very capable of understanding, how the result is to be obtained. It seems unnecessary to adduce concrete instances from the experience of any of the practitioners of orthodox medicine, for we should not know where to stop. It is desirable, however, to point out that modern knowledge of the existence of the "unconscious motive," and of the working of the unconscious mind, teaches us to feel no surprise, still less to postulate any supernormal or occult agency, when an inveterate case of "paralysis" casts aside its crutches and walks. A distinguished physician was wont to impress on his students how frequently the chronic "functional" patient "gets tired of his infirmity," with the natural corollary that he becomes ripe for a "cure," and that "cure" may be effected by any means whatever, physical or spiritual, once the psychological moment arises. The history of the recent war neuroses affords one more proof of the accuracy of this observation. No physician worthy of the name is poor-spirited enough to fail to rejoice when the sick in body and mind are healed by "spiritual" agency; but as he can by ordinary techniques effect identical cures himself and is averse to anything that savours of advertisement he may be pardoned if he tends occasionally to become impatient at the interpretation put on their wonder-working by some self-styled spiritual healers. His hope is that more members of the profession will devote themselves to the relief of the great amount of "floating" nervous ailment that exists to-day, for they possess the immense advantage of knowing what can be influenced by mental methods and what can not, and of being able to recognise and diagnose the ætiological factors that are responsible.

◆

PRESERVATIVES IN FOOD.

THE report, summarised on another page, of the Departmental Committee appointed by the Ministry of Health is an important landmark in the long-drawn-out controversy regarding the use of preservatives in food. For many years the position has been highly unsatisfactory to all parties—consumer, local authority, and food-trader. An inquiry set on foot by THE LANCET in the 'eighties finally resulted in the appointment of a Departmental Committee which made what was then considered an exhaustive investigation.[1] But the report of this Committee, issued in 1901, did not improve matters, for its recommendations (set out on p. 929) never took legal form. They were, in fact, unworkable, since they left the door open to the use of all sorts of new preservatives, except for the few foods specifically mentioned. The present report takes up a perfectly definite standpoint. The trade chemist, as Dr. W. G. SAVAGE has forcibly stated,[2] can always be relied upon to produce other chemical combinations which act as efficient preservatives, and it is futile simply to prohibit specifically-named preservatives. The only effective procedure is to prohibit *all* preservatives, except those in a specified list. If the report is accepted as the basis of legislation all preservatives will now be taboo except sulphur dioxide and benzoic acid, and the use of these will be limited to certain articles and must not exceed prescribed amounts. The report is unanimous that if preservatives are added at all their presence, their nature, and their amount should be frankly declared when the article is sold. Considerable opposition to this was forthcoming, but the Committee satisfied itself that trade interests would not be seriously prejudiced by such a declaration, while the consuming public undoubtedly have the right to know whether or not they are taking preservative drugs with their food. This attitude will be welcome to the medical profession, since there is considerable suspicion, and some evidence, that some obscure disturbances to health may be due to unknown preservatives in the food, and definite declarations as to the presence of preservatives may elucidate the point. Legal difficulties have not been lost sight of by the Committee. To prove that a preservative or colouring matter mixed with an article renders it injurious to health is not an easy, inexpensive, or expeditious matter, and to establish it in one court is not of necessity effective in other instances or in other courts. At present any penalty falls on the retailer, as the person charged, and it is difficult to transfer this penalty to the manufacturer, who is often the real offender. The recommendations as to procedure are intended to remove these anomalies. The proposal that any prohibitions or limitations imposed by the regulations should bind the courts in proceedings under the Sale of Food and Drugs Act is a very important one, since, if adopted, it will only be necessary to prove the actual facts as to infringement.

In arriving at their recommendations the Committee had to consider the other side of the problem which is, how far the addition of preservatives is necessary in the interests of the producer and the community and the extent to which their limitation or prohibition would affect the problem of cheap food. No exact definition of preservatives was attempted, but certain substances, such as salt, saltpetre, sugar, alcohol, are not included, and the term is then interpreted as including "every other substance which when added to food has the property of preventing, arresting, delaying, or masking fermentation or putrefaction of food." In solving this problem the plan which appears to have been adopted was to consider each important food, or group of foods, and after hearing the evidence of the representatives of the trades concerned, to arrive at an opinion as to whether preservatives were really necessary. They considered that trade requirements would be met by allowing two preservatives and those in a limited number of foods, while as regards sausages a concession is made to trade necessities as they exist at present, the opinion being expressed that improved methods should eventually enable preservatives to be dispensed with. The Committee were rightly influenced by the fact that a proportion only of samples of the same kind of food contained chemical preservatives. From this it is an obvious inference that in a good many cases preservatives might be dispensed with, their addition being but a substitute for hygienic precautions and strict cleanliness. As an alternative to the use of preservatives, stress is laid upon the value and utility of the use of cold as a means of preserving food. The prevailing lack of facilities for refrigeration and cold-storage generally is emphasised, particularly in relation to transport. Many of the witnesses examined declared that defective railway transport was one of the main reasons for the use of food preservatives in this country. The Committee which reported in 1901 paid great attention to the subject of the harmfulness of preservatives, although no definite opinion on this subject was included in their recommendations. This aspect appears to have had less influence upon the present Committee and their report cannot be taken as either proving or disproving the harmfulness of the common preservatives in small doses. The difficulties in the way of obtaining proof of harm are so considerable and the evidences of harmlessness are, in the nature of things, so inconclusive that the Committee were well advised to take the broad line that since these substances are injurious in large doses and dosage is uncontrolled, it is justifiable to assume that their presence is undesirable. This is a reasonable standpoint provided that proceedings have not to be taken under Sections 3 or 6 of the Food and Drugs Act, 1875; but, as already mentioned, the point has not been overlooked. It still leaves the problem open as a matter of scientific controversy, but removes it from the heated atmosphere of the law courts.

For practical purposes the report classes preservatives into three groups according to their relative degree of undesirability. Group I., being the most undesirable, includes formaldehyde and its derivatives; hydrofluoric acid, its salts and derivatives. Group II. consists of boron preservatives; salicylic acid and its salts. Group III. comprises benzoic acid; sulphurous acid and their salts. The Committee came to the conclusion that if preservatives are to be used at all in food it is desirable that they should be confined, if possible, to those coming under Group III. Their report, however, refrains from offering scientific evidence in support of this classification. The difficult problem of colouring matter in foods is not solved by the present inquiry. The Committee do not do much more than defer it and recommend that the Ministry of Health should inquire into relative injuriousness and issue a schedule of those substances which may be used. They do, however, adopt the definite standpoint that the addition of colouring matters to foods is to be prohibited, except for those scheduled as harmless, provision being made for the extension of the list on satisfactory evidence of harmlessness. The possibility of toxic impurities, such as arsenic, being present in dyes is given careful consideration, and limits for arsenic are laid down. The prohibition of copper salts as a colouring matter for given vegetables is recommended on the grounds that their use is unnecessary, and that there is evidence that the action of copper salts in small but repeated doses may be prejudicial. From the strictly medical point of view the report may not add much to existing knowledge, but from the public health and administrative standpoints its recommendations, if embodied in legal form, will be invaluable. For the trader they will have the merit of substituting certainty as to what is required of him for the previous uncertainty and the probability of unequal treatment in different areas.

---

JAMAICA AND THE PANAMA CANAL.

THE United Fruit Company, an American commercial undertaking, acting on the enlightened advice of the general manager of its medical department, recently conceived the idea of holding an International Conference on Health Problems in Tropical America. To this conference were invited laboratory workers and clinicians from all over the world, and at the end of last July there gathered at Kingston, Jamaica, a body of men, many of them renowned in the scientific world, who had disregarded the advice of well-meaning friends that a visit to this part of the world in the middle of summer would ruin their health for ever, to discuss certain vital problems of tropical medicine. Amongst them was Sir James Kingston Fowler, who has recorded his impressions in a little volume which has recently been published.[1] After some interesting descriptions of the voyage, the pilot, the climate, and the people, the author plunges into the health problems which affect Jamaica. The prevalent diseases are malaria, hookworm disease, enteric fever, tuberculosis, and, until recent times, alastrim, which, from the preventive medicine point of view, is very similar to small-pox. One of the few bright spots in the sanitary history of the island is the work on hookworm disease. A campaign against this disease was carried out by Dr. B. E. Washburn under the auspices of the International Health Board of the Rockefeller Foundation, and proved a very successful effort. Otherwise, in the words used by the author in reference to the housing conditions in Kingston, "the municipal authorities stand condemned on every count." The U.F.C. wished to be shown how, if possible, the health of their employees could be better safeguarded, but the conference also had the effect, common to all such conferences, of focusing the attention of the inhabitants upon the problems in sanitation which confront them. The U.F.C. has certainly realised that sanitation pays, for whenever it takes over an estate the first activities include the building of a hospital, the erection of mosquito-proof dwellings, and the provision of an efficient water-supply ready for the arrival of the workers. That the inhabitants of Kingston have also been awakened to a "health conscience" seems highly probable from the speech made by the mayor at the dinner which terminated the proceedings when he pointed out that the Government must take up and carry out health measures for the island as a whole and not leave the matter in the hands of many small local authorities. Sir James Fowler discusses the interesting question of whether, with the eradication of tropical disease, such places as Jamaica will ever become suitable and permanent homes for white men and, wisely pointing out that it is the problem of the children which is the crux of the whole situation, he declares himself against the notion that Englishmen will ever be at home in the tropics. He concludes the section on Jamaica with some interesting "suggestions," which include the appointment of a special commission for five years with adequate funds at its disposal to deal with the question of town reconstruction for Kingston, to carry out surveys and laboratory research on malaria and hookworm disease, and to establish an efficient campaign against venereal disease which is appallingly prevalent.

Sir James Fowler entered the Panama Canal Zone with a very effective mnemonic for remembering the position of the principal ports. He left it with some remarkable impressions of the canal as an engineering triumph, and he vividly describes the passage through it of ships, controlled from directing stations at each pair of locks. When H.M.S. *Hood* passed through recently there was only just over two feet to spare on either side between the ship and the walls of the locks, and the fact that the passage was achieved without any mishap is a striking testimony to the skill of those who control the canal. From the health point of view the problem now facing the authorities lies in the fact that the number of employees engaged in connexion with the canal is steadily decreasing and the surplus is being absorbed by settling the men as labourers on the land in unprotected areas. Tribute is paid to the work of General Gorgas in connexion with the protection of the workers from yellow fever and malaria which alone rendered the completion of the canal possible, and it was proposed at the conference in Jamaica to commemorate this heroic worker by erecting an institute to be known as "The Gorgas Memorial Institute for Tropical Medicine." But mainly for economic reasons a change in policy has taken place within the last few years, and it was recommended by the authorities in 1921 that "the amounts expended for sanitation in the zone shall be reduced as much as possible consistent with maintaining the sanitary precautions necessary for the preservation of the health of American employees in tropical service." The result has been that amongst the unemployed labourers who have been settled on the land there has been a large increase in the number of cases of malaria. It appears to be impracticable to sanitate the country in which these settlers live, and already the presence of these men has adversely affected the malaria rate among certain of the workers on the canal and the residential and industrial centres are thus constantly threatened with the danger of infection. Sir James Fowler suggests "with great diffidence" that further research is necessary on the habits of mosquitoes with reference to the length of flight as it affects malarial transmission, and that in future when licences are granted to settlers in the zone it should be enforced that their holdings must be kept free from any conditions which may lead to the breeding of mosquitoes, and that in the place of the usual disreputable shacks, protected houses should be provided for these labourers which they must keep in repair. The work done by General Gorgas and his successors with regard to yellow fever has resulted in the disappearance of this disease in the Panama Canal Zone for 18 years, but

---

[1] An Impression of Jamaica and the Panama Canal Zone. By Sir James K. Fowler, K.C.V.O., C.M.G., M.A., M.D., D.Sc. London: Eyre and Spottiswoode, Ltd. 1924. Pp. 60. 2s.

Sir James Fowler utters a timely note of warning against the use of the word "eradicated" in connexion with this and other menaces to health in the tropics. He concludes his extremely interesting book with a description of the quarantine measures enforced in connexion with the canal, pointing out the danger attached to the modern simplification of procedure in certain cases where wireless is employed, for shipping passing through under any lax conditions may carry plague and malaria, for example, to distant ports. The United States has a moral obligation to the maritime nations of the world to prevent, as far as possible, the passage of disease to other parts of the world, and while this obligation is fully realised there appears to be a certain amount of danger in a system of "quarantine made easy."

Annotations.

"Ne quid nimis."

VOLUNTARY MENTAL PATIENTS.

ELSEWHERE in this issue appears an article by Dr. Edward Mapother, supplementary to his report which we have already noticed,[1] dealing with the first 18 months' work of the Maudsley Hospital. This hospital is unique in being the only institution provided for out of public funds where mental disorder is treated solely on a voluntary basis, and since it is unlikely to remain in this isolated position, its progress is of the first interest to any who are likely to be concerned in following the example set by the London County Council. It is hardly probable that anything amounting to a divorce between the ideas of detention and treatment will take place within the next few years, and the subdivision of mental hospitals into therapeutic centres and houses for the chronic insane is not immediately practicable, but that county and borough mental hospitals should be enabled to admit voluntary boarders may be called almost an immediate probability, and is already occurring in certain parts of Scotland. Nor is it unlikely that under new legislation further hospitals on the lines of the Maudsley will appear in progressive centres. While all may not agree that the recoverable insane are "entitled" to elaborate and expensive treatment, it may well be found that its provision is a national advantage. The supreme question round which Dr. Mapother's argument centres is suitability for the voluntary status. Here we may recall the observations of Dr. Henry Yellowlees at the annual meeting of the British Medical Association this year on the confusion of thought which exists with regard to "early" cases. The adjectives "early," "mild," "recoverable," "borderline," and "hopeful" are used somewhat indiscriminately, but greater variety than may be masked under these far from synonymous descriptions is hardly to be found in the whole realm of mental disease. The early senile dement may be mild and willing, but he is not recoverable; acute mania is eminently recoverable, but it is neither mild nor willing, and may unfortunately require certification for purposes of sufficient restraint, and because noise is, of all annoyances, the one form of disturbance which voluntary patients particularly resent in their companions. "Non-volitional" cases, who form a not inconsiderable class, present a special problem; would it be of advantage to legalise the detention of cases of confusion (in whom, incidentally, the prognosis under efficient treatment is particularly good) without recourse to certification in its present form?

Our whole system of dealing with insanity is at present in the melting-pot. No one can read the report of the sittings of the Royal Commission, of which an instalment appears on p. 909, without realising this. There are literally unlimited possibilities of change in the near future, and the experiences afforded by the Maudsley "experiment"—for so it is—may play no small part in determining our future methods. Details of many of these are to be found in Dr. Mapother's article. Here it is necessary to refer to only three of his main points. The first expresses the intention for which the hospital was built, and which experience has confirmed. "I wish to uphold the view that the aim should be to promote treatment, apart from the certified, of every willing case." The second is that notwithstanding certain gloomy prophecies the hospital has been filled; applicants for admission are increasing in numbers, and as they increase the selection of cases on the ground of amenability to treatment (and for the subsidiary purposes of research and teaching) will yield more and more satisfactory results. Lastly, the "separate treatment of voluntary cases of all degrees of severity" has been found a workable proposition. This, after all, is the most reassuring conclusion which the first year's work at the Maudsley could have been hoped to afford.

LATE ERUPTIONS IN SCARLET FEVER.

Dr. G. Fanconi,[1] of the Zurich University Children's Clinic, has noticed for several years that convalescents from scarlet fever present peculiar eruptions which are not mentioned in the ordinary text-books. The frequent occurrence of these lesions finally induced him to make a systematic examination of the skin of all scarlet fever patients, with the surprising result that 69 out of 74 children examined exhibited these late eruptions. Their diagnostic significance is increased by the fact that they may occur when there is little or no desquamation. Dr. Fanconi has classified these eruptions into the following four groups: (1) maculo-papular, (2) reticulo-rhagadiform, (3) large papular, and (4) pityriasiform. He regards the classification, however, merely as a makeshift, as all possible morphological transitions may occur between these groups. The maculo-papular eruption begins, as a rule, between the tenth and fourteenth day, rarely later, as a bright red punctate or minute papular eruption on the buttocks and extensor surfaces of the knees on either side of the patella, and then invades the posterior aspect and outer side of the thighs and often the flanks as well. The lesions are at first pale pink in colour, but in a few days the rash becomes more intense, especially towards evening, so that on superficial examination it simulates a relapse of scarlet fever. Subsequently the eruption assumes a yellowish-brown tinge and soon disappears altogether, being followed by secondary desquamation. While this variety is chiefly found in children with a smooth skin and little or no primary desquamation, the reticulo-rhagadiform eruption occurs only in association with intense desquamation, being frequently seen on the sides of the abdomen and thorax. It often accompanies the large papular variety which appears in a large proportion of all cases at the end of the first or beginning of the second week in the form of punctate brownish-red macules and papules. Towards the end of the second week some of the lesions become larger and usually assume a violet-red or brownish colour surrounded by a centripetal collarette of ragged epidermis. Lesions of this kind are found on either side of the patellæ, the thighs and sacrum being either isolated or thickly set or even confluent. The pityriasiform eruption which appears on the face at the end of the first week or in the course of the second often affects children who have had a similar skin eruption. It consists of sharply circumscribed, slightly raised lesions covered with white scales, and is most abundant round the corners of the mouth and eyes, while it is much less frequently found on the trunk and limbs. The occurrence of these eruptions is attributed by Dr. Fanconi to three main factors—viz., (1) mechanical irritation of the skin from without—e.g., a late eruption may be artificially produced by the application of sticking-plaster; (2) local skin changes due either to scarlet fever or to previous disease or irritation of the skin; and (3) internal processes, of which another manifestation is an increase of the neutrophil leucocytes of the blood.

BRITISH TRADE IN DANGEROUS DRUGS.

FIGURES have just been issued by the Home Office to show the effect on British trade in morphine and heroin of the restrictive measures which were imposed by the British Government under the Dangerous Drugs Act, 1920, in fulfilment of the International Opium Convention of 1912. The following table gives the amounts of morphine, heroin, and their salts manufactured in this country during each of the last 14 years, and in the case of morphine the quantity exported. The latter information is not completely available in the case of heroin.

Year.	Quantity in ounces of morphine and its salts.		Quantity in ounces of heroin and its salts manufactured.
	Manufactured.	Exported.	
1910 ..	486,975	—	10,272
1911 ..	406,877	208,544	3,785
1912 ..	425,408	276,560	3,034
1913 ..	564,035	406,160	11,665
1914 ..	735,628	504,016	12,249
1915 ..	926,743	295,568	29,756
1916 ..	1,033,162	225,616	26,761
1917 ..	751,851	124,592	46,338
1918 ..	294,703	136,832	34,669
1919 ..	547,347	322,912	84,414
1920 ..	643,985	322,464	76,145
1921 ..	115,734	77,364	12,385
1922 ..	131,028	131,658	31,673
1923 ..	87,940	98,831	11,576

It should be added that the figures given as manufactured are the net amounts of morphine manufactured for use as such, and do not include morphine manufactured for conversion into heroin, codeine, or other alkaloids. The export figures for the years 1911 to 1920 are compiled from the Customs returns and do not include exports by parcel post or exports of preparations containing the drugs. The figures for 1921-23 are compiled from the returns made to the Home Office and include both exports by parcel post and exports of preparations containing the drugs. The export figures for the years 1914 to 1917 do not include exports on Government account between August 4th, 1914, and June 30th, 1917.

PERIODIC ROUTINE MEDICAL EXAMINATION.

IN his presidential address on Oct. 23rd to the Section of Epidemiology, Royal Society of Medicine, Dr. J. C. McVail referred to two directions in which he regarded further progress as possible in the improvement of health and the prolongation of life. One was the merging of medical service under the Poor-law into the general scheme of health administration. The other was the routine medical examination of individuals apart from illness. He recalled the fact that in 1907, at the request of the Royal Commission on the Poor-law, he had investigated Poor-law medical relief in England and Wales, and in his report had urged a system of medical inspection at all ages of life. The family doctor would, not too frequently, but at reasonable intervals, offer to make examination of those for whose health generally he is, or ought to be, responsible. His suggested course of action was sketched out by Dr. McVail as follows:—

1. He would acquaint himself with the general family history. He would note tendencies requiring to be checked—tendencies to general disease like tubercle, gout, rheumatism, diabetes, obesity, cancer, insanity, alcoholism, or the like.

2. With regard to the children, he would note their physical condition as a whole, their state of development in relation to age; indications of rickets, or tubercle, or glandular disease, enlargement of tonsils, defects of hearing and of sight, as bearing on health and education. He would give advice as to diet, bathing, fresh air, exercise, and the like. By prevention of rickets in female children he might succeed in hindering pelvic deformity with its serious results belonging to the child-bearing period of life. In connexion with the occurrence of actual illness, he would be careful to note whether there was any threatening of dangerous sequelæ, such as endocarditis after the acute infectious diseases; or ophthalmia or otorrhœa, which last, if neglected, is often followed, sometimes after an interval of many years, by fatal inflammation of the brain. He would note whether the child's nervous system was being properly developed, on the one hand, and its functional activity sufficiently restrained on the other. As regards the school child, he would see whether school work was being overdone; whether there was headache, or insomnia, or night terrors; whether the child was being taught to practise steady application in any specified task; whether it was being permitted to read books of too exciting or too advanced a character; whether it was being sent sufficiently early to bed, and made to rise early enough in the morning; whether it was being punished unwisely for faults due to its physical and mental condition.

3. As the child continued to grow into youth, the medical man would note whether athletic exercise was excessive; whether injury to the heart or other vital organs was being threatened; whether cycling was being overdone; whether, on the other hand, the youth was leading too sedentary a life and was unduly given to reading. When the time came he would advise as to the most suitable occupation, looking to the general physical and mental health and condition. Amongst girls, he would note tendencies to anæmia, gastric ulcer, and the like, and again, the question of insufficiency or excess of exercise would arise. Here, also, he would advise as to occupation with relation to length of hours and healthiness of employment, whether the work would be too sedentary or require too much standing; whether, as in the case of a teacher, it might involve too severe mental strain or voice strain; whether neuralgia and insomnia would result from the life proposed to be led.

4. Amongst women he would see that due care was taken to prevent mischievous sequelæ of childbirth, such as uterine displacements or inflammations.

5. Among men he would observe any tendency to trade disease, whether their employment was such as made special calls on any of the vital organs, and if so, whether these organs were reacting properly to the stimulus, or were threatening to break down under it. In most cases the important organs would be the heart and the lungs. Heart strain would be looked for, and bronchitis and emphysema and the like.

6. Independently of age and sex and occupation, the inmates of a household would be offered a general examination of their vital organs. In presence of heart lesions, advice would be given in order to prolong the duration of compensation, and to limit the calls made on the heart, so as to give it only so much work as it could properly perform.

7. In old persons attention would be paid to the condition of the arteries in relation to apoplexy, and to parts likely to be attacked by cancerous disease.

Although, Dr. McVail continued, periodical medical examination did not commend itself at that time to the Royal Commission, there had since been remarkable development on the indicated lines. Infant welfare, child welfare, school medical inspection and treatment carried out the principle as regards the young, although the work was not done by the family medical attendant but by school doctors and nurses. As to adult life, progress was now being made. In America several of the large life insurance companies provided for periodical medical inspection of their clients, not on grounds of benevolence, but of economy and finance. It profited them to defer death so that premiums might continue and payment of the life policy be postponed. During the administration of President Roosevelt the system was introduced into the army in respect of commissioned officers, and was reported to be of great value in conserving health. A circular issued by the U.S. War Department in 1921 urged the necessity of the examinations being carried out with thoroughness and attention to detail, so as to enable the Department "to apply practically, on a large scale, the principles of disease prevention and health preservation." The important question, Dr. McVail admitted, was the qualification of the average medical attendant to make skilled examination for the very beginnings of disease. No doubt different skill would be possessed by different men, but if such a system were set on foot there would be steady improvement in fitness for the work. The whole medical curriculum has now been revised with the definite object of permeating the entire period of study by the principle of prevention; every subject from applied physics, chemistry, biology, and anatomy up to the clinical courses is to be taught with a view to the maintenance of health as well as the cure of disease. Teachers desiring to develop a new orientation may find a better field for instruction in the outdoor department or dispensary than in the hospital ward. Dr. McVail concluded by reiterating his opinion that no sphere of medical work was more certain to be helpful in the preservation of health and the prolongation of life than the periodic examination of individuals—of course, with their free consent, the adult for himself, the parent for the child.

INJURIES OF THE SPINAL CORD AND CAUDA EQUINA.

THE Second Report of the Committee upon Injuries of the Nervous System, appointed by the Medical Research Council to deal with and collate the results of experience in this field during the late war, has just been published.[1] Its subject material is the symptomatology and treatment of injuries to the spinal cord and cauda equina. Introductory sections on the applied anatomy and physiology of the spinal cord are followed by a précis of examinational methods and by comprehensive chapters on diagnosis, pathology, and treatment respectively. The report is brought up to date, so to say, by a final section on prognosis, in which it is stated that some 36 patients have been heard from recently, comprising 15 cervical, 19 thoracic, and 2 cauda equina cases of injury. From a consideration of these the conclusion is drawn that "little useful recovery of conduction in the cord, at least so far as voluntary motor power and voluntary sphincter control are concerned, is to be expected after the lapse of a very few months, although long after that time improvement in function can be brought about by physiotherapy, mechanical aids, and the many methods of re-education and training." During the war our knowledge of the functions of the spinal cord was materially increased by a study of the phenomena resulting from section of the cord by high-velocity projectiles. We learned that old chapters on the clinical sequelæ of total transverse lesions would have to be rewritten; that so far from outfall of function being a characteristic of the isolated spinal cord, it might live and express its activity by clinical signs such as the automatic bladder, involuntary reflex movements of the lower extremities, and the presence of the deep and cutaneous reflexes for these limbs. Some of these reflex movements, not specifically mentioned in the report, are of considerable scientific interest and perhaps of biological significance, in particular those associated with the sexual mechanism. We may note incidentally in passing that the report appears to have omitted reference to priapism and its treatment in its otherwise practically complete survey of the symptomatology of spinal-cord injuries. How long the isolated spinal cord is capable of functioning is possibly more of theoretical than of practical interest; it would appear, however, that there are cases where some of the lower cord segments, completely severed from the upper cord, are living in activity now, nine years after the injury. The descending degeneration that we were taught constantly set in after severe cord injuries is apparently less likely to ensue on clean-cut high-velocity lesions than with crushing lesions of the "fall of coal on the back" type. Under the term "spinal concussion" the Committee properly include cases of a definitely organic character, in which recognisable changes are to be found in the cord, while the clinical symptoms—those of spinal shock, viz., loss of motor power, diminution or loss of reflexes, impairment of sphincters, &c.—begin to disappear within a few days, or may persist for several weeks. Doubtless it is impracticable to draw any hard-and-fast line between the slight and the pronounced grades of concussion, and in not a few instances of genuine commotio (a term not employed by the Committee) the symptoms begin to clear up within some hours, not days, yet the authority of this report should help to dispel the common and erroneous idea that the familiar symptoms of a traumatic neurosis following blows or knocks on the spinal column are the result of "spinal concussion," "spinal commotion," "spinal irritability," and what not. Spinal concussion as a clinical expression is misused as much as influenza. A further point in this connexion concerns the matter of progression or otherwise of the symptoms. It is a known histopathological fact that reparative processes set in after spinal concussion; the œdema, minute hæmorrhages, focal areas of necrosis, damage to nerve cells and fibres, all eventually tend to vanish, and a perfect clinical recovery is the rule. If, accordingly, after an injury that is of quite minor degree, the symptoms not only do not clear up quickly but actually increase as time goes on, only two diagnostic alternatives are possible; either the injury has accentuated a latent organic spinal condition, recognition of which is always easy by proper examination, or else the state is a non-organic one and purely psychical, to which the injury as such has contributed literally nothing from the standpoint of ætiology. The sections on treatment, both surgical and medical, are particularly useful and thoroughgoing. Anyone who reads the paragraphs on the treatment of the paralysed bladder, bedsores, and the other distressing symptoms of spinal disease, will learn much that will help him to alleviate, if not to cure, these difficult complications. The Committee frankly acknowledge the absence of any complete solution of the problem of treatment in the matter of severe spasticity with involuntary flexor and extensor spasms; they mention the usefulness of certain drugs, such as luminal-sodium and hyoscine, but there is no reference to veronal as an antispasmodic, though it has often served in this respect. Surgical procedures (crushing the obturator nerves, resection of dorsal roots, &c.) are described without much comment on their efficacy or otherwise. The report represents the combined experience of those who are qualified to speak, and as such may be recommended to the profession at large.

BIOCHEMISTRY AT GREAT ORMOND STREET.

THE Hospital for Sick Children in Great Ormond-street has decided to allocate some recent gifts of money to the installation of a biochemical department. This was opened on Oct. 23rd, at a meeting at which the chair was taken by Mr. John Murray, who made an eloquent appeal for further funds to extend and endow the department. He was supported by Dr. G. F. Still, Dr. F. J. Poynton, and Dr. D. N. Nabarro, the last named showing some slides indicating the importance of vitamins in relation to rickets and scurvy. At the conclusion of the meeting the new department was thrown open for inspection. The necessity for the appeal became apparent on visiting the laboratories. They consist of converted rooms of the hospital, which may suffice for immediate needs, but which allow no room for expansion. The position was admirably summed up in a remark, made by a member of the honorary staff, "only an Englishman could work here." That Englishman is Dr. G. A. Harrison, the new biochemist, to whom we wish every success. With such splendid clinical material the coöperation of clinician, pathologist, and biochemist must result in great advances. That there is ample room for such is shown by the almost complete lack of chemical observations on diseases of children in the literature of this country. At the same time it is awise for the public to be directed to the biochemist the magician who will deliver them from their toils. he belief is growing that if only a man who can iggle with blood and a colorimeter can be set to ork all the insoluble problems of medicine will fade way. Every decade in the history of medicine has en associated with some specialised branch, through hich it was hoped to find the solution to most or all the problems of the day. The institution of the ience of morbid anatomy by Morgagni marked a eat advance in the knowledge of the time, with the sult that it was thought that the ultimate solution the majority of medical problems lay in the dead ouse. When the broad lines of this mode of investi- ation had been worked out, it was eclipsed by irchow's work on cellular pathology. Nothing was lked of but histological research, and it appeared that e complete medical horoscope could be cast through e microscope. This in turn was displaced by acteriology, whilst to-day biochemistry strides pidly to the front. The pioneers of all these move- ents have themselves been modest men, realising at their discoveries stand out, by contrast, as right stars against a background of ignorance. iochemistry is even now becoming a hack word, and nless a reasoned conception of its aims, objects, and robable attainments be held, the science will sink into iscredit. The public utterances of certain distin- uished pure chemists have thrown out a salutary arning. But the fact remains that the older clinical ad pathological observations stand in great need of pplement by more delicate means.

THE BANANA AS AN ACCESSORY FOOD.

THE vitamin content of the banana has already been e subject of research, and it seems to be generally greed that this fruit contains large quantities of -vitamins and a not negligible quantity of B-vitamins. here is not such unanimity of opinion with regard to he presence of A-vitamins, and it was with a view to hrowing further light on this matter that Dr. Eva opp, of the Kapp Laboratory, undertook the following ivestigations.[1] About 25 young rats, each weighing om 30 to 40 g., were put on an A-vitamin-free iet, on which they were kept till they began to lose eight and show signs of A-vitamin deficiency. After ost of them had developed advanced xerophthalmia hey were classed in three groups, each of which eceived a different ration of banana in addition to he basal A-vitamin-free diet. The rats in the first roup were given as much banana as they could eat. fter a fortnight, during which they made little rogress, rapid improvement was observed in the ondition of the eyes, which in most cases were per- ectly healthy when this experiment had lasted 10 to 2 weeks. After the rats had been on the banana diet r three weeks their general condition improved reatly, there was a uniform gain of weight, and they ere full grown by the time the experiment was rought to an end. The rats in the second group were iven only 1 g. of banana daily in addition to the asal A-vitamin-free diet. It was anticipated that his banana ration would be insufficient to restore the ats to normal health, but to Dr. Sopp's surprise the ats in this group fared practically as well as those in he first group. The rats in the third group were iven 2 g. of banana daily, and they also throve n this addition to the A-vitamin-free diet. Dr. Sopp raws the interesting conclusion that 1 g. of banana to a young rat as four or five whole bananas are to three-year old child, and that with even less than ur or five bananas a day it should be possible to rovide a young child with a sufficient supply of -vitamins. In addition to its high and varied itamin content, the banana possesses many virtues, rominent among which are its pleasant taste and igestibility. It contains from 19 to 20 per cent. of ugar and starch, and from 0·5 to 1 per cent. of fat, not to mention 4 to 5 per cent. of protein. With so much to its credit, it is to be hoped that the banana will remain within reach of the modest purse.

THE LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN.

THOSE who planned the functions designed to celebrate the jubilee of the London (R.F.H.) School of Medicine for Women deserve credit for organising such a varied programme. The dinner at the Guildhall was on a grand scale, the service at St. Paul's was impressive, and the evening party at the school was just friendly. At this party, where the whole of the quadrangle of the school appeared to be enclosed in one huge marquee, and all the buildings were open to visitors, mimes and concerts and a dance were held; some of the lay visitors might have felt still colder—for it was a chilly night—if they had realised the normal occupations pursued in the room where they enjoyed the plays, grave and gay, performed by the students. Cheery greetings and nicknames were shouted across well-remembered corridors, and possibly the past students found this party where old friends foregathered the most entertaining part of the celebrations. To outsiders, on the other hand, St. Paul's Cathedral crowded so that no vacant seat could be discovered, by men and women largely in academic dress, all assembled to give thanks for opportunities of service, was an imposing spectacle. The passage in the order of service which riveted attention was as follows:—

> Through the ages there have been women in spirit born before their time. They had vision and faith, and by their toil and sacrifice, by their persistence and courage, opportunities for women in training, work and service have been won. Three Pioneers opened the doors of Medicine to Women: ELIZABETH BLACKWELL, ELIZABETH GARRETT ANDERSON, SOPHIA JEX BLAKE. With love and reverence our hearts turn to them.

The duty of commemorating these three women was the main subject of a speech delivered the night before at the Guildhall dinner by Miss L. Aldrich-Blake, the Dean of the school, when she spoke of the intention to collect money to endow university chairs in physiology, pathology, and anatomy to be named after them. Miss Aldrich-Blake paid a tribute also to those far-sighted and fair-minded men who as individuals or as members of official societies or bodies had helped generously and gladly in women's medical emancipation. The toast of Women's Work was proposed by the Dean of St. Paul's, that evening in cheerful vein, and responded to more seriously with fine delicacy by Lady Barrett and Mrs. Fawcett. Prof. E. Gardner, Vice-Chancellor of the University of London, toasted the school, and its Dean, in responding, handed to the chairman of the Royal Free Hospital a Roll containing the names of new subscribers and donors secured by past and present students during the jubilee year. It fell to Prof. Winifred Cullis to propose the most popular toast of the evening, that of the chairman, Mrs. Scharlieb, M.D., who is president of the school. Mrs. Scharlieb was a touchstone whom not to know was not to be a member of the school, for she made herself a personal friend of staff and students, and in herself combined tradition, achievement, and inspiration. The large company of medical women, students, and their guests rejoiced with loud applause at this apt expression of what Mrs. Scharlieb means to medical women, and we would join them in the hope that their illustrious president will be spared to see still greater development and prosperity of the school.

AT the recent sitting of the new Dental Board it was resolved to notify dental practitioners with addresses in the Irish Free State that the Dentists Acts no longer apply to that part of the British Dominions, and that, unless they desire to practise in places where these Acts are in force, they are not compelled to have their names retained in the Dentists Register.

---

[1] Norsk Magazin for Laegevidenskaben, September, 1924.

WE learn that the 1924 Nobel Prize for Medicine and Physiology has been awarded to Prof. Willem Einthoven, of Leyden, Holland, for his discoveries in connexion with the mechanism of the electrocardiograph.

NOMINATIONS for Direct Representatives to the General Council for the period 1925–29 must be made before next Thursday, Nov. 6th. The four nominees of the British Medical Association for England and Wales are Dr. R. A. Bolam, Dr. H. B. Brackenbury, Dr. J. A. Macdonald, and Sir T. Jenner Verrall. Dr. F. H. Westmacott is standing as an independent candidate. Their election addresses will be found on p. 935, along with a letter endorsing the candidature of Sir Norman Walker as Direct Representative for Scotland.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XCIV.—THE TREATMENT OF PRURITUS ANI.

PRURITUS ani is the commonest form of localised itching of the skin. It is more frequent in men than in women, and may occur in children, though its incidence is greatest in middle-aged folk of sedentary occupations and in old age when it is often associated with general atrophy of the skin. It is relatively commoner in private practice than in the hospital clinic. Pruritus ani is a subjective symptom of some general or local condition and is not a disease *sui generis*. It is therefore essential, before determining what treatment we should adopt in any given case, to discover first, if possible, its cause and then to remove it or neutralise its action.

General Causes.

Gout is, perhaps, the commonest general cause, for pruritus ani not infrequently alternates with acute attacks of gout. Rheumatism and diabetes, too, are at times responsible for its onset and should receive appropriate treatment. Disorders of the liver, constipation, and impaired digestion, due to over-indulgence in rich foods, may also be exciting factors. Constipation must be treated on general medical lines; aloes, in consequence of its irritant action on the rectum, should not be prescribed. A bland but nutritious diet is indicated. Condiments, pickles, rich sauces, and highly seasoned dishes should be forbidden. Strong coffee and alcohol, except in the strictest moderation, are contra-indicated. Certain other articles of diet—e.g., shell-fish and strawberries—appear at times to provoke attacks and are therefore tabooed. Excessive smoking should be prohibited. When the patient is in a low state of depression and the appetite poor, or there is evidence of neurosis, tonic treatment (quinine and nux vomica) is indicated, together with outdoor exercises—golf, riding, cycling, &c. If there is sleeplessness, bromides, sulphonal, or chloral hydrate may be administered cautiously. In the obviously neurotic case a straight talk may do much good, whilst in some hands hypnotic suggestion has met with marked success.

Local Causes.

Local causes are more often responsible than general ones. The commonest are: catarrh of the rectum with consequent offensive discharge, best treated by injections of warm boric acid lotion; threadworms, the commonest cause of pruritus ani in children, occasionally persist in the adult and should be removed by enemata of strong solutions of common salt or of quassia, followed, if necessary, by 2 to 5 gr. of santonin and a purgative; hæmorrhoids, which should be operated on; polypi and ulcers. Fistulæ if present should be slit up, and any cracks and fissures touched with the caustic pencil or by painting with a 10 per cent. solution of silver nitrate in spt. æther. nit. Warty excrescences should be snipped off. Excessive sweating and tumours in the rectum and pelvis which obstruct the venous circulation are possible causes, and diseases of the genito-urinary apparatus may be either the direct or reflex cause of pruritus ani. Incomplete evacuation of the bowels, and especially want of cleanliness about the anus, should be looked for. *Cleanliness* of the parts after defæcation may be procured by the removal of fæcal matter or mucous discharge with pledgets of cotton-wool moistened with water. After drying a bland dusting powder should be applied. Morning and evening washings with hot water and coal-tar soap are to be commended. The application of a sponge wrung out in hot water sometimes has a very beneficial effect and may procure a night's repose.

Pruritus ani is often very resistant to treatment, but most cases are curable if taken in hand early and if the cause be located. The ailment is too often looked on as a trivial matter. If treatment is delayed until the skin has become indurated, excoriated, and sodden, then, even though the cause be removed, the itching will persist, since the nerves remain in an excitable state due to the pressure exerted on them by the fibrosed skin. It is imperative, therefore, that a careful general and local examination be made before any method of treatment is instituted. Not until after such an examination has been made are we justified in classifying a case as neurotic. The neurosis may be induced by the pruritus ani and the cause still be active though unrevealed. Each case must be dealt with in accordance with the findings and with the idiosyncrasy of the patient.

Persistent or Residual Itching.

Having removed the apparent "cause" without relieving the symptoms, or having failed to find any general or local pathological condition, we are left with the further treatment of the patient. There are many vaunted remedies, but the most expert physician cannot invariably foretell which, if any, will benefit the case in hand. It is necessary to proceed with patience and caution. Whether ointments or lotions will afford the greater relief is impossible to foretell; in spite of statements to the contrary, ointments are frequently of the utmost service.

Carbolic acid often acts like a charm. It may be used as a lotion (1 in 80) or as a liniment (1 in 20 of olive oil), and compresses soaked in these applications used as the symptoms demand. It may be combined with sodium hyposulphite in a lotion, or with cocaine or mercury in ointment or lotion form—e.g., Acid. carbol., gr. xv.; cocainæ hydrochlor., gr. x.; paraffin. moll. ad ℥i. Acid. carbol., gr. xii.; cocainæ hydrochlor., gr. x.; aq. laurocerasi, ʒiii.; aq. rosæ ad ℥i. Acid. carbol., gr. xx.; hyd. perchlor., gr. ii.; ol. lini., ʒi.; paraffin. moll. ad ℥i.

When the itching is intense or when it extends within the rectum, a half grain *cocaine suppository* affords untold relief, but such treatment should be cautiously adopted, especially in a neurotic patient. I have found the ung. gallæ cum opio equally efficient.

Cycloform ointment (5 per cent. with lanoline base) and 5 per cent. *anæsthesin* ointment are also helpful.

Tar has its advocates. The sapo carbonis detergens is desirable for washing the parts and the liq. carb. deterg. or the liq. picis carb. ʒii.–ʒiv. to the pint of water as a lotion. In an ointment combined with mercury and salicylic acid I have found it most useful—e.g., Acid. salicyl., gr. xv.; liq. picis carb., ♏xx.; hydrarg. ammon., gr. xv.; paraffin. moll.; adipis lanæ hydr., āā ℥ss.

Mercury is the most useful antiseptic, either in an ointment (calomel ʒss. ad ℥i. of vaseline or hydrarg. ammon., gr. xv. ad ℥i. of benzoated lard) or in the following lotion: Hydrarg. perchlor., gr. iii.; glycerini, ʒv.; aq. chloroformi, ad ℥x. After the morning toilet calomel in powder may be dusted on the parts.

or, better still, rubbed into the affected region by the patient. After the daily evacuation of the bowels the patient is instructed to clean and dry the parts and then to rub in 20 gr. of calomel. Such treatment, repeated for a few days, has in some instances produced most gratifying results.

Various means may be adopted for reducing the thickening of the peri-anal skin. *Salicylic acid* (6 per cent. in 50 per cent. alcohol) may be used as a paint. Twenty-second applications of *solid carbon dioxide*, with a simple protective ointment afterwards, may also be used. Carefully painting the parts with pure carbolic acid and applying Lassar's paste to the raw surface resulting from the subsequent exfoliation is an easy and convenient method. A more drastic means, necessitating a general anæsthetic, advocated by Mitchell Banks, is the use of the actual cautery to effect a superficial burn. The operation is followed by the use of the lotion of bicarbonate of soda (1 in 8) as a soothing medication and the application of zinc cream. These latter methods necessitate keeping the patient in bed till the parts are healed, and I seldom resort to them.

X Rays.

Radiation by means of the X rays I now use as the routine method of treatment for pruritus ani. Not only have the rays a marked anti-pruritic action, but they also reduce induration of the skin. X rays seem to have entirely superseded surgical division of the nerves, and not a few cases which have recurred after operation have remained permanently well after but a few exposures to the X rays. The treatment should only be undertaken by a careful and competent radiotherapeutist, for over-exposure will produce a far greater evil and bring a valuable therapeutic agent into undeserved condemnation. Four unfiltered doses of a half pastille each are given at fortnightly intervals, and then after a month's rest two further exposures if necessary. The surrounding parts should, of course, be efficiently protected. An antiseptic ointment or lotion is prescribed when the circumstances demand.

The high-frequency *electrode* has proved efficient in some neurotic cases. Dr. J. M. H. MacLeod speaks well of *zinc ionisation* where superficial abrasions are present. The ionisation has definite astringent and anti-pruritic properties. MacLeod describes the procedure as follows: "A piece of lint the size of a penny is soaked in 2 per cent. sulphate of zinc solution and applied to the affected skin, the positive pole of the battery with a solid zinc electrode is pressed against the lint, while the negative electrode is held by the patient, and a current of a few milliampères is passed for ten minutes."

Vaccines.

Some few years ago the late Dr. D. H. Murray, of Syracuse, N.Y., met with considerable success by the use of autogenous vaccines made from the *Streptococcus fæcalis*. His results have been confirmed by other American observers, but this treatment has not met with much approval in this country. Latterly, however, Dr. C. E. Jenkins, of Manchester, has adopted it with favourable results in a small series of patients. Dr. Jenkins gives seven injections at weekly intervals, using a residual vaccine. This method seems worthy of further trial in obstinate cases. It should not, however, be adopted before all other pathological conditions have been excluded.

LOUIS SAVATARD, L.S.A. Lond.,
Hon. Physician, Manchester and Salford
Hospital for Diseases of the Skin.

EASTBOURNE EAR, NOSE, AND THROAT HOSPITAL.—At the annual meeting of this institution on Oct. 24th the governors reported that the reserve fund had been increased to £1750. The needs of the hospital were growing. During the year the number of out-patients was 2257 and the in-patients 268. The number of operations performed was 245. The balance-sheet showed a balance to be carried forward of £120. Mr. T. Garton Jenkins was re-elected president.

Special Articles.

ON THE QUESTION OF BIRTH CONTROL IN SOME OF ITS STATISTICAL ASPECTS.

BY JOHN BROWNLEE, M.D., D.SC. GLASG.,
DIRECTOR OF STATISTICS, MEDICAL RESEARCH COUNCIL.

I PROPOSE in this paper to examine some of the statistics relating to population in England and Wales. This population is at present tending to become stationary. Prof. Bowley has recently shown that with a birth-rate equivalent to the average of the three years 1921–23 and a death-rate similar to that in 1911, the population will attain a maximum about 1971 and thereafter slowly decline, the maximum for Great Britain being 49,000,000 as against 42,700,000 in 1921. It is unlikely that this maximum will be attained as it is most probable that the annual number of emigrants will be at least 120,000, in which case a maximum population at a lower level may be reached in the course of 15 or 20 years.

The discussion falls under three headings: (1) the relation of a high birth-rate to infantile mortality; (2) the age at marriage in relation to fertility; and (3) how far the fall in fertility in the last 50 years has reduced the chance of the country becoming more seriously over-populated than it is at present.

Relation of High Birth-rate to Infantile Mortality.

The question of the relation of the infantile mortality to the birth-rate has been the subject of inquiry by a number of statisticians. Of these it is only necessary to refer to Dr. Major Greenwood.[1] In his paper on this subject in 1912 he shows that the correlation between the infantile mortality and the birth-rate varies very largely according to the method in which the calculations are made. Thus if the crude birth-rate is taken, the correlation is 0·81; if the birth-rate is based upon all women between the ages of 15–45 years it falls to 0·64; if it is based upon wives aged 15–45 years it becomes 0·53, while the corrected birth-rate, as given by Stevenson and Newsholme, gives a correlation of 0·36. He also found, taking the birth-rates based on all women at the ages 15–60 years in districts of Bavaria, that the correlation was 0·68. Dr. Greenwood, however, in this paper was investigating certain social problems and not making a special inquiry into the actual influence of infantile mortality on fertility or the reverse.

I am doubtful whether there is any real relationship between infantile mortality and fertility. Of course, it is probable that a high infantile mortality, by limiting the duration of nursing may permit a few extra births, but even supposing that the infantile mortality were 200 per 1000, the increase in the number of births due to this would be at most somewhere in the neighbourhood of 1 in 10 and the differences found in different districts are very much greater than this. To investigate the relationship is, however, difficult in the sense that the fallacies due to the use of any known method have not been sufficiently examined. Further, it is necessary to select data which are not open to the suspicion that restriction of birth is being practised. If present-day statistics were chosen, as there must be more restriction of births among the better classes, where the infantile mortality is low, a correlation between high fertility and high infantile mortality would at once be obtained. To use such figures is to work with loaded dice. To avoid this difficulty I have gone back to the statistics of 1871, when the birth-rate of England was about its maximum and when figures may be said to be free from the objection just noted.

---

[1] Greenwood, M., and Brown, J. W.: An Examination of Some Factors Influencing the Rate of Infantile Mortality, Journal of Hygiene, 1912, xii., No. 1.

I have confined the inquiry to districts north of the Humber and the Dee because the infantile mortality south of this region obeys a different law, and if the south of England were to be considered it must be taken by itself. The northern counties referred to contain 131 registration districts of very varied character, the infantile mortality varying from 78 to 220, a very wide range. The crude birth-rate, that commonly taken as the measure of the fertility, is here of no use because the towns of these districts in 1870 contained a very high percentage of young married women. The proportion of legitimate births to the married women between the ages of 15 and 45 years is a better guide, but requires correction, as the proportion of young married women to older married women at child-bearing ages varies very markedly from town to country. The application of a fertility factor as advocated by Stevenson and Newsholme gives a better measure, but the consequences of using this fertility factor have not yet been thoroughly worked out. Two sets of fertility-rates are known for this country, that for the cities of Glasgow and Edinburgh, given by the Registrar-General for Scotland and used by Dr. Matthews Duncan for the year 1855, and that given for Aberdeen for the Census year of 1911 by Dr. M. Hay. In association with these may be placed the Swedish fertility-rates used by Stevenson and Newsholme. The three sets of figures are given in Table I. The figures measure the chance that a married woman at each age bears a child within a year. It will be noticed that among married women between 15 and 20 years of age the fertility in the three sets of figures is the same, but the rate of decline with age differs considerably. Prof. Tait long ago noticed that the rate of decline in fertility follows very closely a straight line, and for purposes of calculation it may probably be taken as a straight line without introducing any very serious error. To use fertility ratios, the numbers of married women at each age-period were taken out for each registration district in the region indicated and also the numbers of legitimate births for the three years 1870, 1871, and 1872. The fertility figures of Dr. Matthews Duncan were multiplied into the corresponding numbers of married women and the theoretical number of births calculated and compared with the average number of births in the three years in question. The ratio of the actual births to the theoretical was then calculated, and this ratio I call for the purpose of this paper the "fertility ratio."

TABLE I.—*Fertility-rate among Married Women at Different Age-periods.*

Age of the mother.	Edinburgh and Glasgow, 1855. (Dr. Matthews Duncan.)	Aberdeen, 1911. (Dr. Hay.)	Sweden, 1911.
15–19	0·5000	0·5000	0·5181
20–24	0·4179	0·3740	0·4514
25–29	0·3464	0·3250	0·3753
30–34	0·2656	0·2060	0·3118
35–39	0·2039	0·1450	0·2504
40–44	0·0804	0·0690	0·1423
45–49	0·0127	0·0080	0·0200

Secondly, as the decline of fertility in these three cases is very nearly a straight line, and as its starting value is the same, it has been assumed that this holds in all districts. Thus, if the fall in fertility with each period of five years be denoted by D, the fertility between 15 and 20 years is taken as 0·50, that between 20 and 25 years becomes 0·50 −D, between 25 and 30 years, 0·50 −2D, and so on. Applying these ratios to the number of married women and comparing with the number of births, it is easy to obtain the value of D for each district. This value I call for the purpose of this paper the "fertility constant."

Other factors, however, come into this inquiry. One of these is the density of population. This has been measured in the calculations by the logarithm of the number of acres per person in each district, as it is found that this measure gives linear regressions. Another factor already referred to is the proportion of young married women to those married at fertile ages. This has been measured by taking the proportion between 15 and 25 years to the total number of married women between 15 and 45 years. It would have been more satisfactory to have made the division at 30 years, but the statistics for this age are not available. A third important factor is the proportion of married women at fertile ages to the whole population.

We are now in a position to examine the results obtained under these conditions and to discuss thereafter what trust is to be placed in their accuracy. Taking the "fertility ratio" measured as described above, it is found that the correlation between this and infantile mortality is high and negative, being equal to −0·497, that between the infantile mortality and the "fertility constant" as described above, −0·301, while that between the ratio of the births to the married women between 15 and 45 years of age and infantile mortality is +0·248. These different methods thus give very various answers. Both the infantile mortality and the fertility are, however, very highly correlated with the number of acres per person. This factor determines both high infantile mortality and low fertility, the correlation being, respectively, −0·855 and +0·619. It may be noted that this relation of density of population to fertility is in exact accordance with Prof. Pearl's experiments with the fruit-fly *Drosophila.*[2] When the partial correlation coefficient between the fertility and the infantile mortality, keeping the logarithm of the acreage per person constant, is calculated, a coefficient of +0·08 arises. Another measure of the degree of urbanisation is the proportion of married women between 15 and 45 years of age to the total population. If, then, the fertility and infantile mortality are correlated, keeping the proportion of married women constant, the partial coefficient of correlation becomes −0·11. Taking next the "fertility constant" and infantile mortality and making density constant, a correlation coefficient of +0·19 is obtained. The remaining correlation—namely, that between the proportion of births to married women at fertile ages and infantile mortality—changes in the same way. Here the disturbing factor is the proportion of young married women to the whole married at fertile ages, the proportion in the country being considerably lower than in the towns. When this factor is made constant the correlation coefficient becomes −0·13 (Table II.). Thus, with three different measures

TABLE II.

First correlations.	Partial correlations.	First correlations used in calculating partial correlations.
	$r_{FI.M} = -0{\cdot}11$	$r_{-DA} = +0{\cdot}455$
$r_{FI} = -0{\cdot}497$		$r_{MI} = +0{\cdot}772$
	$r_{FI.A} = +0{\cdot}08$	$r_{FM} = -0{\cdot}569$
$r_{-DI} = -0{\cdot}301$	$r_{-DI.A} = +0{\cdot}19$	$r_{IA} = -0{\cdot}855$
$r_{BI} = +0{\cdot}248$	$r_{BI.W} = -0{\cdot}13$	$r_{MA} = -0{\cdot}799$
		$r_{FA} = +0{\cdot}619$
		$r_{WI} = +0{\cdot}622$
		$r_{WB} = +0{\cdot}539$

A = Logarithm of the number of acres per person.
I = Infantile mortality.
B = Ratio of births to married women aged 15–45 years.
F = Fertility ratio.
D = Decline for five-yearly period in fertility: to be measured as −D.
M = Proportion of married women at fertile ages to total population.
W = Proportion of wives under 25 years of age to the whole married women at fertile ages.

---

[2] Pearl, R., and Parker, S. L.: On the Influence of Density of Population upon the Rate or Reproduction of Drosphila, National Academy of Sciences, vol. viii., No. 7, pp. 212–219.

of fertility, when certain corrections are made, the four values of the partial correlation coefficient are all in the neighbourhood of zero, which is the value of the average. It may thus be said that the connexion between fertility and infantile mortality is at least very small.

This result is, I think, important. It strikes straight at one of the arguments for limitation of a family—namely, that it is better, say, to have three or four healthy children than five or six unhealthy. Conditions being equal, the size of the family has nothing to do with the infantile death-rate.

The Age at Marriage in Relation to Fertility.

The next point to be considered is how far fertility has been influenced by the age of marriage. This I discussed recently in THE LANCET,[3] but take the advantage of using the figures of the 1921 Census to bring the matter up to date. It is commonly stated that at the present moment the age of marriage has risen. To test this I have taken the percentages married at the different age-periods in the 1911 Census and applied these ratios to the numbers of women living at each age-group registered in the 1921 Census. It will be seen that if the numbers married between 15 and 30 years had been as in 1911, there would have been 1,337,100 married women between 15 and 30 years of age, whereas the number enumerated was 1,411,900, the latter being much in excess. In the same way the corresponding figures for married women between 30 and 45 years is 3,214,900, as against 3,184,000. The figures for each age-group are given in Table III. Thus, instead of the population at the present moment having a higher age at marriage it has a lower. Consequently, this factor does not come in as producing a decline in the birth-rate.

TABLE III.—*Numbers of Married Women in Hundreds Estimated on the Theory that the Percentage at Each Age Married in 1911 was Maintained and those Actually Found by Enumeration.*

TABLE IV.—*Numbers of Married Women in Hundreds in the Life-Table Population of 1911, the Total Population being Taken as 36,000,000.*

III.				IV.		
Age.	1911.	1921—		Age.	Total.	Population of females married.
		Theoretical as in 1911.	Actual.			
15–19	201	212	311	15–19	13,838	165
20–24	4,041	4,114	4,597	20–24	13,638	3,294
25–29	9,064	9,045	9,210	25–29	13,410	7,487
30–34	10,570	10,694	10,595	30–34	13,140	9,251
35–39	10,154	11,056	10,893	35–39	12,807	9,619
40–44	8,735	10,399	10,351	40–44	12,397	9,355

The Birth-rate in Relation to Population.

The number of births which might be expected from the population of 1921 now falls to be considered. Using the fertility figures employed by Dr. Stevenson and Sir Arthur Newsholme in their investigations—namely, those for Sweden in 1891, figures which closely represent the facts in England in 1871—there should be 1,338,000 legitimate births. Taking Dr. Hay's figures for Aberdeen in 1911, the number becomes 942,000. The average actual number of legitimate births for the three years about the Census is 800,000, but for the year 1923 the births only numbered 727,000. The ratio of the present fertility of England to that of England in 1871 is thus 0·55. The fall in the birth-rate is still going on, for the number of legitimate births in the first two quarters of 1924 is 372,000, as against 390,000 last year.

It now remains to consider the distribution of a birth-rate necessary to maintain a stationary population. For this the determination of the "fertility constant" seems to be the only method. When the "fertility constant" is determined with the number of births in 1923 and applied to the Census population of 1921, it is found to be 0·105 in place of 0·060 in 1871. We thus apply fertility-rates, 0·500, 0·395, 0·280, &c., at the successive age-periods.

Let us now consider a life-table population. The necessary data are contained in the life-table for 1910–1912, calculated by Mr. King. The total population has been assumed to be 36,000,000, as in 1911. Assuming the same marriage constitution of the population as in 1921, the number of married women at each age has been calculated (Table IV.). The application of the fertility-rates given at the end of the preceding paragraph to this life-table population of married women gives 607,000 legitimate births. To this total the proportion of illegitimate births has to be allowed for, raising this number to 632,000 births. The number of births required to maintain a constant population of 36,000,000, which is a life-table population in the health conditions of 1911, is 675,000, so that the fertility of 1923 would not suffice to maintain the population on the basis of health of 1911. The infantile mortality has fallen, however, very considerably. Taking a very liberal allowance in this regard by assuming that the infantile mortality may be taken as 60 in place of 120, as in 1911, a smaller number of births will suffice to maintain the population. As a matter of fact, with this allowance it works out at 632,000, the exact figure just obtained.

The difficulties of the future in this country are very great. Without emigration the population is bound to increase for a time, and with 1,000,000 people out of work that seems a very serious prospect. But if the fertility declines much further, a more serious problem will ultimately arise. Nothing like a stationary population in the life-table sense can, of course, be expected for a very long period. At present a larger elderly population requiring maintenance is steadily accumulating, while there is a smaller proportion of persons at working ages. The prospect instead of being one which tends to a higher standard of living, would seem almost necessarily to lead to a lower.

Conclusion.

The results of this investigation are, I think, three.

1. When the data are taken before restriction of birth became a practical factor, there is no evidence that large families were more unhealthy than small ones, and the statement that it is better to have three healthy children than six unhealthy ones has no apparent foundation.

2. That in place of marriage taking place at a higher age, it has, probably due to the war, taken place at a lower age than in 1911, so that the population is in a more favourable condition for the production of children now than then.

3. That in place of this being the time for preaching control of birth, the opposite is the case. The time for preaching birth control has passed. Whether due to birth control or not, and I think the much larger part of the fall is due to race physiology, the birth-rate has reached the level required, and any further fall will very seriously endanger the national life.

MEDICAL GOLFING SOCIETY.—The autumn meeting was held at Princes', Sandwich, on Oct. 18th and 19th. Seventy members took part in the competitions, and the meeting was a very successful one. All competitions were played under handicap. The results were as follows: Best Return *v.* Bogey (cup presented by Mr. Ernest Clarke, the President): T. H. P. Kolesar, C. Ilott, and C. E. Finny, all square; won on replay by Mr. T. H. P. Kolesar. Foursomes *v.* Bogey (prizes presented by Dr. J. Grace): E. Ravensworth Hart and H. W. Carson, and H. D. Gillies and W. H. Lamplough; won on replay by the first-named couple. Canny Ryall Cup (Medal play): H. D. Gillies, 72 + 2 = 74; G. S. Moriarity, 87 – 8 = 79.

[3] THE LANCET, 1922, ii., 223.

THE STAR AND GARTER HOME

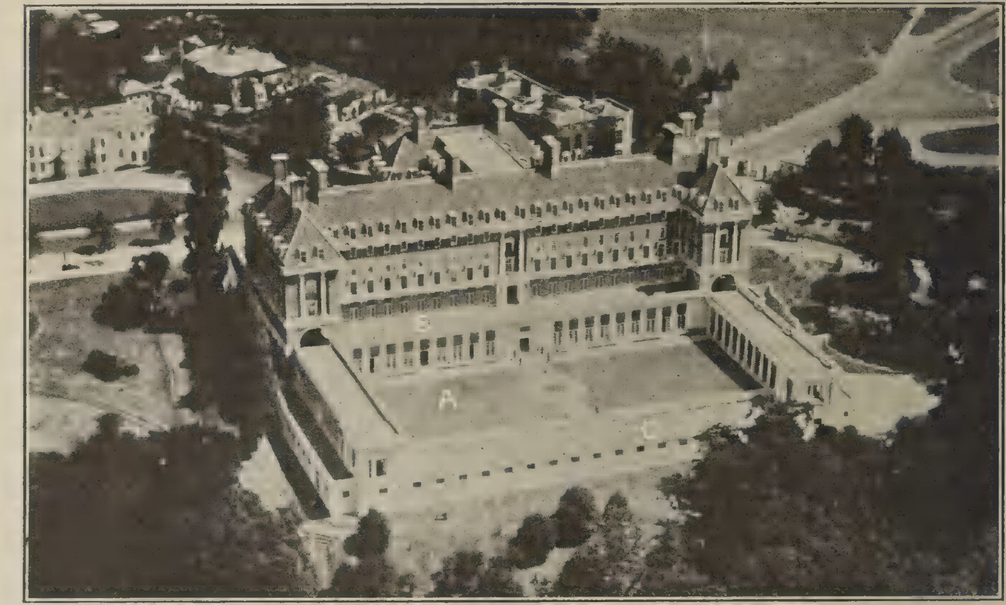
FOR DISABLED SAILORS AND SOLDIERS.

(By a Special Correspondent.)

This beautiful Home, in its unrivalled position on the banks of the Thames at Richmond, Surrey, has been built to provide comfortable, it may almost be said sumptuous, accommodation for some 180 disabled and paralysed men of the Services. It has taken six years to build. The money for the site was found by the Auctioneers and Estate Agents' Institute, and for the building by the British Women's Hospital Committee. It is maintained by an endowment fund formed by contributions from the "Women of the Empire." It is thus the "Women's Memorial of the Great War." Sir Edwin Cooper, the hon. architect, has built for these poor fighting men, broken in the wars, a palace rather than a mere hospital, and he has kept ever in view the needs of the stretchers, beds, and wheeled chairs, to which so many of the inmates are condemned for life, by providing wide doors, uninterrupted floors, broad bed terraces, and so on. The main entrance is at the Richmond Gate of Richmond Park, and opposite to it is Ancaster House, which has been remodelled within to be a nurses' home at one end, and at the other a residence for the commandant, Lieut.-Colonel E. L. Gowlland, R.A.M.C.

On the upper ground-floor is the 24-foot wide memorial entrance-hall, which runs through the building to the bed terrace; polished slabs of Italian marble from Subiaco form the floor and walls, the roof being supported on 14 monoliths of the same material. The great marble staircase opens off the hall to the right, while on the left will stand the marble group, "Patriotism Recording Sacrifice," below three coloured windows representing St. George, Faith, and Charity. On each side of the hall are electric automatic lifts to carry beds, and beyond are two lofty 18-bed wards, about 40 ft. by 80 ft., giving plenty of space for nursing. Each man has a bed-table with a second shelf and two drawers. The beds have 8-inch rubber-tyred wheels at the head end, and handles at the foot, hinged to fall and be out of the way when not required, so that the nurse can easily wheel a patient to and from the bed terrace, even if a water-bed is being used. There is direct access to the terrace through wide casement doors. Each patient has his own bell, ringing to the nurse's room, and is provided with an electric-light switch and an overhead bed-lift. There is a power circuit plug by each bed to facilitate electrical treatment. The ward lavatories are on the north side, projecting into an inner court, and cross ventilation of the ward has been arranged. The south side of the ward opens in its entire extent on to the bed terrace, 21 ft. wide and 220 ft. long, whence the renowned view over the Thames valley can be enjoyed in fine weather. On this upper ground-floor also, on either side of the entrance-door, there are, to the right, the matron's office, diathermy, electrical, and other treatment rooms, the X ray department, the operating theatre, the clinical laboratory, and a ward of four beds with its annexes. On the left are the administrative offices, the dispensary, and another ward of four beds. On the north there is a mezzanine floor for staff dining rooms, stores, telephone exchange, and quarters for the steward and engineer.

The Star and Garter Home, Richmond.



The Chapel (c) is seen in the foreground with the Garden Terrace (A) behind and the Bed Terrace (B) looking down upon it.

[*Photo by Aerofilms, Ltd.*

Below this is the lower ground-floor, where are the patients' dining-room, 94 ft. by 54 ft., and 20 ft. high (giving ample space for each patient, though so many are in wheeled chairs), and the common room of similar size facing south-west and opening on to the garden terrace lawn, which lies between protected colonnades or loggias. In the servery attention was directed to a convenient handle for the larger table-drawers, a wooden bar running nearly the whole length, so that the drawer can be opened either with one or both hands, the bar serving also as a towel rail. Adjoining the common room, which is supplied with newspapers, there are a canteen and a library containing already over a thousand books. At the outer corner of each of these rooms is a cosy "quiet" room, as comfortable and well furnished as the members' smoking room in a good club. The northern side of this floor is occupied by stores, &c. The main kitchen, measuring 50 ft. by 50 ft., has a great floor space and is well equipped, well lighted, and thoroughly ventilated. In the sculleries teak sinks are used to diminish breakage of crockery. They are said to give satisfaction, and to be no harder to clean than the usual fire-clay pattern. Below the garden terrace to the left front of the Home is the Cowdray Memorial Chapel, given in remembrance of Lord Cowdray's son, killed in the war. It is in marble, with an ever-open grille in the door allowing a glimpse of the altar from the outside. On the ground-floor there is also a recreation room with a billiard table, in which kinematograph exhibitions may be held, further the Zander room with mechanical massage and exercising machines, and beyond these are the workshops for employing such patients as may be possible. On this floor also are the mortuary and the post-mortem room. There is a garage for patients' hand-wheel and motor bath-chairs; on the day of my visit one, electrically propelled, had just been received. The boiler room contains two Lancashire boilers, coke-fired, for the heating of the establishment. All water is softened (Permutit system) and there are calorifiers in two sets, one providing hot water for the lavatory supply, the other for the radiators throughout the building.

On the first floor are the residential quarters of the matron and the secretary, and a sitting-room for nurses. The rest is for the accommodation of patients, mostly in single rooms, each of which is supplied with a fixed basin. The second and third floors are wholly devoted to patients. The fourth floor is entirely for the accommodation of the staff. Here in quiet are the rooms for the night nurses, the others having their rooms in Ancaster House, across the road, where they have a garden and tennis-court. As the patients demand much nursing the nursing staff is large. On the fifth floor is an isolation and observation ward. Ventilation has been most carefully considered. The entire building is of fire-proof construction. The furniture and cabinet work throughout is of Japanese oak, designed by the architect, highly finished, and most comfortable. Electric lighting is taken from the local supply company.

In inspecting a hospital it is often rather hard to be sure of the quality of the meals, but your correspondent got an eminently satisfactory statement from one of the patients: "The boys are tickled to death at the food, they never get the same thing twice." The profession may rest assured that here is, in fact, a worthy home for heroes.

PRESERVATIVES IN FOOD.

FINAL REPORT OF THE DEPARTMENTAL COMMITTEE.

IN July, 1923, Mr. Neville Chamberlain, then Minister of Health, appointed a Committee to inquire into the use of preservatives and colouring matters in food, and to report—(1) Whether the use of such materials, or any of them, for the preservation and colouring of food, is injurious to health, and, if so, in what quantities does their use become injurious; (2) whether it should be required that the presence of such materials, and the quantities present, in food offered or exposed for sale should be declared.

The members of this Committee were: Sir Horace Monro (chairman), Prof. W. E. Dixon, M.D., F.R.S., Sir David Hall, F.R.S., Dr. J. M. Hamill, Mr. O. Hehner, F.I.C., Prof. F. G. Hopkins, M.B., F.R.S., Dr. G. R. Leighton, Dr. A. P. Luff, Dr. C. Porter, Mr. G. Stubbs, F.I.C., with Mr. A. M. Legge, of the Ministry of Health (secretary). Mr. P. A. Ellis Richards, F.I.C., later took the place of Mr. Hehner.

This Departmental Committee issued an interim report[1] on the treatment of chilled beef and other foods with formaldehyde, and has now brought in its final report,[2] which is unanimous except in one small particular.

The Committee met on 41 days and heard oral evidence from 101 witnesses, including medical officers of health and public analysts, physicians, pharmacologists, pathologists, chemists, and a great number of persons connected with the trades which would be affected by any restrictive action in connexion with the use of preservatives or colouring matters in food, including manufacturers, importers, wholesale dealers, and retailers.

Recommendations of the 1899 Committee.

In 1899 a Committee was appointed by Mr. Chaplin, then President of the Local Government Board, with Sir Herbert Maxwell as chairman, to inquire into the use of preservatives and colouring matters in food and their effect on health. The report of this Committee was issued[3] in 1901 (Cd. 833). The preservatives then stated to be in use were very much the same as those now employed in this country, viz.: Boric or boracic acid and borates, Sulphurous acid and sulphites, Fluorides (to a very limited extent), Benzoic acid and benzoates (to a very limited extent), Salicylic acid, Formalin or formaldehyde.

The recommendations which this Committee made were as follows:—

(*a*) That the use of formaldehyde or formalin, or preparations thereof in foods or drinks be absolutely prohibited, and that salicylic acid be not used in a greater proportion than 1 gr. per pint in liquid food and 1 gr. per pound in solid food. Its presence in all cases to be declared.

(*b*) That the use of any preservative or colouring matter whatever in milk offered for sale in the United Kingdom be constituted an offence under the Sale of Food and Drugs Acts.

(*c*) That the only preservative which it shall be lawful to use in cream be boric acid or mixtures of boric acid and borax, and in amount not exceeding 0·25 per cent. expressed as boric acid. The amount of such preservative to be notified by a label on the vessel.

(*d*) That the only preservative permitted to be used in butter and margarine be boric acid or mixtures of boric acid and borax, to be used in proportions not exceeding 0·5 per cent. expressed as boric acid.

(*e*) That in the case of all dietetic preparations intended for the use of invalids or infants chemical preservatives of all kinds be prohibited.

(*f*) That the use of copper salts in the so-called greening of preserved foods be prohibited.

(*g*) That means be provided either by the establishment of a separate Court of Reference or by the imposition of more direct obligation on the Local Government Board to exercise supervision over the use of preservatives and colouring matters in foods, and to prepare schedules of such as may be considered inimical to the public health.

The report was unanimous save that one member of the Committee considered that an amount not exceeding half a grain of metallic copper per pound might be permitted in preserved vegetables, its presence being in every case declared.

Action Taken in Other Countries.

The report summarises in general terms the action taken in different countries with regard to different preservatives:—

(i) Every country or State which has legislated on the subject of preservatives prohibits the use of fluorides and formaldehyde as preservatives.

(ii) Boron preservatives are absolutely prohibited by the United States of America and by Sweden. They are permitted specifically, in certain dairy products only, in Australia, New Zealand and Canada, while their use is apparently tolerated to some extent in Holland.

(iii) Sulphur dioxide is prohibited in meat or meat products in every country whose laws and regulations we have had the opportunity of studying, except in New Zealand and in the draft regulations which have been recently under consideration by the States of the Australian Commonwealth, where it is allowed in minced meat and certain meat preparations. The restrictions are generally less severe in the case of the preservation of fruits and fruit products, and sulphur dioxide is commonly permitted in wine, beer, cider and non-alcoholic drinks in limited amounts.

(iv) Benzoic acid is rarely referred to, but is permitted generally, subject to declaration, under the Federal law of the United States; in Canada except in meat and subject to a limit of 1 part in 1000 and to declaration of its presence; in Australia in the same quantities and products as sulphur dioxide; in Denmark in sausages, and in Uruguay in canned meats and meat products.

---

[1] THE LANCET, August 16th, p. 329.

[2] H.M. Stationery Office. 1*s*. 6*d*.

[3] THE LANCET, 1901, ii., 1682.

(v) Salicylic acid is permitted in a few instances, sometimes as a substitute for sulphur dioxide, in concentrations varying between 1 in 5000 and 1 in 3500.

No country, except Japan and certain of the United States of America, is absolutely intolerant of preservatives of any kind in all foods, but the extent to which preservatives are limited by law seems to indicate that the problem of keeping foods without resort to chemical preservatives has not been generally found to be insoluble. As regards colouring matters copper is prohibited in green vegetables in the United States of America, and in Australia, Canada, and New Zealand; under the laws of other countries which deal with the subject the amount permitted is generally limited to one part in ten thousand, equivalent to 0·7 gr. per pound. Switzerland and Japan have published lists of prohibited colours, and Belgium lists both of prohibited and of permitted colours. Other countries, including the United States of America, Uruguay, Sweden, Canada, Italy, Spain, France, Denmark, the Australian States, and New Zealand, have issued lists of permitted colours, with power to add to the lists. The number of synthetic colours permitted varies between 10 permitted by New Zealand and 21 allowed under the French law.

General Principles.

The report starts from the basis of three propositions, considered to be generally accepted: (1) That it is undesirable to add to articles of food any material not of the nature, substance, and quality of food; (2) that if for commercial or other reasons the addition is necessary, it should be limited to the minimum required to effect its purpose; (3) that if it can be shown that some of these materials are less undesirable than others, preference should be given to the employment of the less undesirable materials.

Definition of Preservative.—In the term "preservative" the Committee does not include salt, saltpetre, sugar, vinegar, acetic acid, alcohol and spices, or the minute quantities of preservative agents introduced by the process of curing known as "smoking," nor does it include substances which, though they may have some preservative properties, are added to food for other than preservative purposes, and in the amounts in which they may be used in food possess preservative properties in so slight a degree that they cannot be regarded as commercially practicable preservatives. The term "preservative" is interpreted in the report as including every other substance which when added to food has the property of preventing, arresting, delaying, or masking fermentation or putrefaction of food.

The first proposition stated is self-evident. The report deals in succession with the question of the possible risk to health from the chemical action on the human body of the substances employed as preservatives. Apart from such risk these substances may mask unsoundness in food or be a cloak for careless or inexpert methods of production, storage, or distribution. It is recognised that the problem is not simple. Great Britain is in some ways peculiarly situated. A large proportion of the food of her people is imported, much of it from long distances, and on arrival at the ports has to be distributed to all parts of the country, while the provision of cold storage and cold transport is far less than in some other countries. Home producers have urged that the ultimate point in cleanliness and the maximum of efficiency have been attained in their factories, and yet the food cannot be relied upon to keep for the necessary period between preparation and consumption without preservatives. Nevertheless the Committee is confident that in the case of many foods trade methods could be adjusted to eliminate preservatives without serious inconvenience to traders or consumers.

Conclusions and Recommendations.

Permissible Preservatives.—After a consideration of all the evidence the Committee concludes that preservatives should be prohibited in all articles of food and drink offered or exposed for sale whether manufactured in this country or imported, *except that:*

(*a*) *Sulphur dioxide* only should be permitted (1) in sausages in amounts not exceeding 3 gr. per pound; (2) in jam in amounts not exceeding 0·3 gr. per pound; (3) in dried fruit in amounts not exceeding 7 gr. per pound; (4) in preserved (but not dried) whole fruit or fruit pulp in amounts not exceeding 5 gr. per pound; (5) in beer and cider whether in bottle or in cask in amounts not exceeding 5 gr. per gallon; (6) in alcoholic wines, non-alcoholic wines and cordials, and fruit juices, sweetened and unsweetened, in amounts not exceeding 3 gr. per pint.

(*b*) *Benzoic acid* only should be permitted (1) in coffee extract in amounts not exceeding 3 gr. per pound; (2) in non-alcoholic wines and cordials, and sweetened and unsweetened fruit juices (as an alternative to sulphur dioxide), in amounts not exceeding 5 gr. per pint; (3) in sweetened mineral waters and in brewed ginger beer in amounts not exceeding 1 gr. per pint.

Sale of Preservatives.—The sale of any preparation as a food preservative or for use in such circumstances that it may be introduced into food should be declared illegal unless such preparation (*a*) bears a description clearly indicating its composition and strength; (*b*) is free from impurities and in particular contains not more than 1/100th part of 1 gr. of arsenic per pound or more than 1/7th part of 1 gr. of lead per pound.

Declaration of Nature and Quantity.—The use of preservatives so far as they are permitted should be upon the condition that the nature and quantity of the preservative present in the article of food should be declared[4] in a manner prescribed by the Minister of Health. In cases in which the declaration of the preservative might be difficult to enforce or might result in undue harm to the industry without compensating advantage to the consumer, exception to this requirement might be made, but the exception should in no circumstances apply to sausages.

Copper Salt.—The employment of a copper salt to colour or preserve the colour of peas and other vegetables should be prohibited.

Schedule of Colouring Matters.—A schedule should be issued by the Minister of Health after such inquiry as is necessary of colouring matters the use of which may be considered non-injurious to health, such schedule to be subject to amendment or extension from time to time as occasion may require. Within a suitable period after the publication of this list the use of any other colouring matter should be prohibited unless and until it shall have been approved by the Minister.

Period of Grace.—Before the prohibition of preservatives or of colouring matters in food (including the use of copper salts for the so-called greening of vegetables) is enforced, a period of grace should be allowed sufficient to enable manufacturers and importers to adjust their methods and processes and to allow stocks to be cleared.

Storage and Transport.—Improved methods in the storage and transport of food by rail, road and water, especially as regards the use of refrigeration and cool-air storage, are urgently required.

---

[4] Sir David Hall regards it impracticable from a trade point of view and unnecessary for the protection of the public health to enforce a declaration of the presence of the permissible quantity of sulphur dioxide in beer, cider, wines, and mineral waters.

Regulations to Bind Courts.—It should be provided by law that any regulations or statute prohibiting or limiting the use of preservatives and colouring matters should bind the courts in proceedings taken under the Sale of Food and Drugs Act in respect of their use.

Expedited Prosecution.—An amendment of the law is required to render more expeditious the prosecution of a person actually responsible for offences under these Acts, where a warranty defence is pleaded.

Right of Inspection.—Further powers of control by registration, licensing, or inspection should be given to local authorities in relation to all places concerned in the production, sale, storage, and distribution of food.

Amendments of Law.

The Committee regards the present position of the law in regard to preservatives and colouring matters as far from satisfactory. Under the Sale of Food and Drugs Act, 1875, the proof that a preservative or colouring matter mixed with an article renders it injurious to health is not an easy or expeditious matter and when established in one court is not necessarily effective in other courts. Expert evidence is given on both sides, and the court has to decide on the conflict of evidence whether an offence has or has not been committed. Each case has to be decided on the evidence laid before the particular court, as to the probability of injury to health, and there is no recognised standard by which the court is bound. Neither traders nor local authorities nor the public can definitely know what is permissible under the law and what is not. Many authorities hesitate to undertake prosecutions under the present law except in cases where the amount of preservative used is grossly excessive. For instance, the previous Departmental Committee in 1901 recommended that the limit of boron preservative in cream should be 0·25 per cent., the Local Government Board in 1917 adopted a limit of 0·4 per cent., the presence of 0·3157 of boric acid per cent. was held at the Clerkenwell Quarter Sessions in 1913 to be injurious, while other authorities do not proceed unless the amount exceeds 0·4 per cent.

Whatever may be the actual measure of control taken, the Committee regards it as eminently desirable that it should be clearly embodied in regulations having the force of law. Any prohibitions or limitations imposed by the regulations should bind the courts in proceedings taken under the Sale of Food and Drugs Acts. If this were done, traders and the public generally would know what was permissible and what was not, and there would be no conflict of expert evidence on the question whether the amount of preservative or colouring matter was or was not injurious to health.

Improved legal means for dealing with offences connected with the adulteration of food would not, the Committee considers, quite cover the whole ground. The suggestion that sulphur dioxide might be permitted as a preservative in sausages needs a special safeguard against the risk that tainted ingredients may be used in their manufacture, the unsoundness of which may be masked by the preservative. Such permission could only safely be accorded if local authorities are empowered to inspect the places where such articles are prepared, together with the methods of preparation and the materials used. Cleanliness of materials and methods is a matter of prime importance in the production of food, and the use of preservatives is apt to tend to the perpetuation of bad methods. If suitable regulations were made for securing ventilation, cleanliness of premises and appliances, the use of clean and wholesome materials, and the like, in all places where food is prepared and retailed, including eating houses and restaurants, a great deal would be gained. Coupled with the power to make such regulations there should be a power of inspecting all places to which the regulations apply.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Royal Medical Society of Edinburgh.

THE inaugural address of the 188th session of the Royal Medical Society of Edinburgh was delivered on Oct. 17th by Sir Ronald Ross, K.C.B., director and chief of the Ross Institute and Hospital for Tropical Diseases, London. Dr. A. B. Williamson, the President of the Society, was in the chair. Sir Ronald Ross took as the title for his address Thoughts on Medical Discovery. He said that a brief study of civilisation showed discovery to be a rare phenomenon, tending to be localised both in place and time. The Græco-Roman period of discovery lasted about nine centuries, and following it there came a long negative period of about 11 or 12 centuries in the course of which practically no advances of any kind were made. In the fourteenth and fifteenth centuries came the renaissance simultaneously in almost every line, in art, literature, science, exploration, and philosophy, a renaissance which had lasted up to the present day. Sir Flinders Petrie's hypothesis as to the cause of these periodic augmentations of intellectual vigour was that they followed the admixture of races by permeation or conquest. The vigour of a people began to increase some centuries after permeation with a foreign race; art and science were born or re-born, and then came regression and decay, followed by subsequent invasions and conquests. It was, indeed, unlikely, said the speaker, that all the world's nations could be at the same stage of development. India and China to-day were in the slack stage as compared with Europe, and Europe was approaching the slack stage as compared with America. Sir Ronald Ross held that medical discovery was to human beings the most important of all kinds of discovery. Yet, to judge by the public attention given to it, it was the least important. Men handed it over to the doctors and were good enough to allocate almost no money for the prosecution of it. The total amount provided for research every year in this country was, he said, probably only £180,000, a sum which represented a contribution of a penny per head for England, Scotland, and Wales, and this was for a science concerned with the life and health of all the people. For this penny everyone hoped to have his life prolonged. Life had been prolonged in the last 80 years in London from an average of 40 years to 60 years, and he did not see why the average expectation of life should not reach the 70 years of the psalmist. It was not known why elephants and parrots and tortoises lived for more than a century, while horses and dogs died before 20, and he said he had often wondered what would be the length of life of an individual kept entirely free from pathogenic organisms and certain deleterious foods and drinks. Doctors and every man of science might congratulate themselves that almost the whole of medical discovery had been made without the help of anyone and at their own expense, but the world would be wise to spend much more money than it was now doing in order to fight diseases of all kinds by investigating how they might be fought. The country had to pay millions of pounds for the prevention of foot-and-mouth disease, largely because it refused to pay small sums for the investigation of the disease. Sir Byrom Bramwell moved a vote of thanks to the lecturer, which was seconded by Dr. W. McKie.

University of Edinburgh.

At a recent meeting of the University Court of Edinburgh University it was announced that an ordinance had been approved by His Majesty in Council whereby medical students who have passed an approved examination in any of the subjects of the first or second professional examination at any other university in the United Kingdom or elsewhere, may have such passes counted as equivalent to passes in Edinburgh University, subject to the approval of the Senate and the Court.

At the same meeting a letter was read from Miss Margaret C. Tod, M.B., Ch.B., who graduated with first-class honours in July, 1924, intimating that she did not feel justified in accepting the considerable sum of money granted to her in scholarships and prizes and requesting that the amount be added to the D. R. Wardlaw Memorial Fund for necessitous students. The Court resolved to accept Dr. Tod's offer.

IRELAND.

(From our own Correspondents.)

Irish Free State: The Local Government Bill.

The Minister of Local Government and Public Health has found that so many amendments to his Local Government Bill would be necessary that he has decided to withdraw the Bill introduced last session and bring in an entirely fresh measure. In reference to this the Minister, Mr. Burke, with some of his principal officers, gave an interview last week to a deputation from the Irish Medical Committee. The members of the deputation were Drs. J. M. Day, H. Raverty, P. J. Shanly, and T. Hennessy, with Mr. C. H. Gick. Sir James Craig also attended and took part in the discussion. The following is a brief summary of how medical officers will probably be affected if the Local Government Bill becomes law:—

1. Section 8 of the Local Government Act, 1919, with its mandatory provisions for pensions, will be allowed to stand for all existing medical officers who within a prescribed time, which may be three or six months, elect to come under this section for the purposes of their pensions. It is believed, however, that the basis for calculating the amount of pensions will be so altered as to secure a more uniform standard.
2. Added years for meritorious and professional service will remain optional, with the right of appeal to the Minister.
3. Pensions of medical officers appointed after the passing of the Local Government Bill will be as heretofore permissive, but in case of refusal by a local authority, or dispute as to the amount, the right of appeal to the Minister will be provided for. It was pointed out on behalf of the Ministry that there is no mandatory provision for pensions for civil servants, and that the appeal to the Minister will place medical and other officers of local authorities on the same footing as civil servants with regard to pension rights.

In addition to the pension sections other matters arising out of the Bill were discussed, and the Minister promised to give them his consideration.

Royal Victoria Hospital, Belfast.

The session was opened on Oct. 16th, when there was a large attendance of students and of the medical staff. The opening address was delivered by Prof. W. W. D. Thomson, who paid a tribute to those friends of the hospital who had passed away during the previous year—Viscount Pirrie, Sir John Walton Browne, and Miss Riddell. He surveyed the field of clinical medicine, emphasising the fundamental importance of bedside observation, and concluded with an interesting analysis of the careers of those students who had begun their medical studies with him 20 years ago. A hearty vote of thanks was passed to the lecturer for his valuable and instructive address on the motion of Prof. J. A. Lindsay, seconded by Colonel T. Sinclair.

Dr. William Calwell and Dr. H. L. W. Kisack have retired from the active staff under the age-limit and have been appointed consulting physicians to the hospital. The board of management passed a very cordial vote of thanks to them for long and faithful services. They have been the recipients of a presentation of silver plate from their colleagues on the staff, by whom they were entertained at dinner. Their successors on the active staff are Prof. W. Thomson and Dr. Foster Coates. To fill the vacancies thus created in the out-patient department Dr. Robert Marshall and Dr. Samuel I. Turkington have been appointed assistant physicians.

The entrances at the Belfast Medical School this session show some decline on the previous session's figures, but are considerably in excess of the pre-war figures.

The Health of Belfast: Annual Report for 1923.

The most notable feature of the recent health history of Belfast has been the rapid decline in typhoid fever. Thirty or forty years ago the disease was very rife, and in one year the deaths numbered no less than 500. In the year 1904 the deaths were at the rate of 0·30 per 1000 of the population. In 1908 the figure had fallen to 0·15 per 1000. In 1909 there was a drop to 0·05 per 1000, and in the period 1919–22 the figure was 0·04 per 1000. In 1923 the figure had fallen to 0·01 per 1000. This rapid and satisfactory decline was coincident with the inauguration of the present excellent water-supply, which is chiefly derived from the large storage basins in the Mourne Mountains. Diphtheria seems to be about stationary. The notifications for 1923 were 289, but of these 48 were found not to be suffering from the disease. The average number notified for the decennial period 1913–22 was 289, and deaths in 1923 numbered 24, as compared with an average for 1913–22 of 34. Scarlet fever continues to be very prevalent. The number of cases during the past year was 981, as compared with 744 in 1922, and an average for 1913–22 of 1440. Of the 20 cases of encephalitis lethargica notified in the report for 1923, three were fatal. The deaths from cancer numbered 391, as compared with 363 in 1922. Influenza accounted for 100 deaths, as compared with 241 in 1922. The deaths from phthisis were 571, as compared with 624 in 1922. Pneumonia accounted for 564 deaths, as compared with 594 in 1922. The report contains full particulars of the sanitary improvements effected during the year. Progress is well maintained.

PARIS.

(From our own Correspondent.)

The Thirty-third French Surgical Congress.

The thirty-third French Surgical Congress which was recently held in Paris was eminently successful both from the point of view of attendance of members and from the character of the discussions which were held. The President, Prof. Tuffier, opened the Congress with a paper on the modern conception of surgery. He said that surgery was based on a firm tripod of technique, observation, and experiment, and the keynote of development was precision. Dr. Auvray, who took on the office of general secretary, paid a tribute to his predecessor, Dr. J.-L. Faure, and in the name of the Congress welcomed a delegation of 30 Polish doctors, headed by Dr. Zawadski, of Warsaw. Three main subjects came up for discussion during the Congress. The first was the treatment of simple fractures of the upper extremity of the femur and their ultimate results. Mr. Dujarier, of Paris, and Mr. Léon Imbert, of Marseilles, read a well-informed paper on the different methods of treatment of fractures of the neck of the femur. They discussed operative treatment and non-operative treatment. Of the latter the following methods were described: (1) Championnière's method—namely, a very short stay in bed with extension and massage from the commencement; (2) continued traction; and (3) Whitman's method—namely, accurate reduction followed by retention in plaster-of-Paris. The second subject for discussion was the indication for surgical treatment in uterine fibroids. Mr. Tixier, of Lyons, set forth the conditions in which surgical treatment was the only possibility. The mortality from operation was about 4½ per cent. (576 deaths in 12,893 cases), of which 2 per cent. were due to infectious complications. Other causes which too frequently caused death were the sequelæ of anæsthesia and vascular complications, such as phlebitis, hence it was necessary to improve both technique and pre- and post-operative treatment. Surgery should be conservative as often as possible. The ideal should be myomectomy, thus preserving the form and function of the uterus, a thing to be aimed at even in the case of elderly primiparæ, as the natural ovarian secretion was insufficient to cope with the disorders of a precipitated menopause. Where the intervention was not conservative it must be radical, and the procedure of choice was total hysterectomy. In very young women, in order to leave the anatomical form of the vagina intact, subtotal hysterectomy might be performed. Mr. Labey, of Paris, then spoke of the different forms of operation, both in the pregnant and the non-pregnant woman.

The third subject for discussion was pre- and post-operative care and the choice of an anæsthetic in gastro-intestinal surgery, on which Mr. Lambret, of Lille, and Mr. Lardennois, of Paris, had prepared a paper. One meeting of the Congress was given over to kinematographic demonstrations, showing the technique of removing the cancerous breast by Mr. Depage and Mr. Davis, of Brussels, laminectomy by means of a new nibbling forceps by Mr. Davis, two methods of cosmetic surgery of the breast by Mr. Dartigues, of Paris, and the technique of operations for correcting defects of the nose by Mr. Dufourmentel, of Paris.

The Fourth Pediatric Congress.

The Fourth Congress of the Association of French-speaking Pediatrists was recently held in Paris at the Sick Children's Hospital under the presidency of Prof. Marfan, assisted by Dr. Henri Barbier, the general secretary. There were three subjects of discussion, the first being the treatment of purulent pleurisy in children, on which Dr. Ribadeau-Dumas, of Paris, and Dr. Rocher, of Bordeaux, had prepared a report. In the child the effusion was purulent in one-half or one-third of all cases, while in the adult it was only seen in about every fifteenth case. The different treatments employed for this condition were reviewed by the speakers. The variety in the methods of treatment adopted was to be explained by (1) the many different types of purulent pleurisy; (2) the state of the patient; (3) the state of the lung; (4) the age of the subject; and (5) by the type of the organismal infection. The evacuation of pus must be promoted by all medical resources available, such as chemotherapy, serotherapy, and vaccinotherapy. Extensive drainage by resection of the ribs ought to be avoided. Purulent pleurisy in very young children required conservative measures, such as aspiration and syphon drainage. The low infectivity of pneumococcal infections was well known. For these infections the treatment indicated was repeated aspiration, which might be followed by some therapeutic injection. In tuberculous effusions conservative treatment was indicated, and in other cases pleurotomy. The second subject for consideration was the prophylaxis and treatment of infantile syphilis. Mr. Léon Tixier read a paper in which he discussed hereditary syphilis in all its aspects, and dealt with the question of authorising marriage between syphilitic individuals and of the treatment to be adopted during pregnancy. He advocated the supervision of parents and children with a view to avoiding the consequences of hereditary syphilis. For the suckling he advised a combination of mercury, arsenic, and bismuth, administered alternately. When the child was weaned the treatment differed little from that of the adult. The exhibition of small initial doses avoided fatal accidents, especially if care was taken not to give intravenous injections to cachectic children. The ease with which mercurial inunctions could be carried out was not a sufficient reason for preferring them to more efficacious measures when such could be applied. The third subject comprised the study of the ætiology and pathogenesis of rickets. MM. Lesné, de Gennes, and Vagliano, of Paris, referred to the results obtained from animal experiment, and stated their conclusions from the study of human rickets. Human rickets appeared to have a very different source of origin from that of experimental rickets. For example, deficiency of phosphorus and calcium was not found to be a basic factor, while syphilis and tuberculosis seemed to be a relatively rare element in ætiology. On the other hand, much greater attention must be paid to digestive troubles of early childhood as a causal factor. In spite of the obscurity which still existed in regard to the ætiology and pathogenesis of rickets great benefit was gained by treatment with solar radiation, ultra-violet rays, and cod-liver oil. These three measures formed the most effective therapeusis both from the curative and the preventive aspects.

The Congress of French-speaking pediatrists will be held in future every second year, alternately in Paris and outside France. The next is fixed for Lausanne in September, 1926.

Annual Statistics of Recently Qualified Doctors.

The number of diplomas of doctor of medicine issued by the French Medical Faculty during the academic year 1923–24 was 1124, an increase of 130 on the number issued in the preceding year. The figures vary greatly in the different schools. Paris leads with 496, then come Lyons (152), Bordeaux (133), Montpellier (103), Toulouse (53), Lille (45), Algiers (43), Strasbourg (42), Nancy (29), and the French Medical Faculty of Beyrouth, Syria (28). These figures refer only to the State diploma—that is, the diploma which gives the right to practise medicine in France. The University diploma, which is reserved for foreigners, is a purely academic one, and does not confer any of the rights and privileges attached to the status of doctor as given by a State diploma. The number of these diplomas granted by French universities during the academic year 1923–24 was 165.

UNITED STATES OF AMERICA.

(From an Occasional Correspondent.)

The Use of Insulin.

It is somewhat disappointing to find that the discovery of insulin has not yet checked the increasing death-rate from diabetes in this country. On the contrary, diabetes achieved last year, for the first time in the statistical history of New York City, the distinction of a place among the first causes of death. The Metropolitan Life Insurance Company, naturally interested in this apparent failure, has investigated the histories behind 500 certificates giving diabetes as the cause of death. They made the surprising discovery that only 45·4 per cent. of these had received any insulin at all. Of the minority receiving insulin, one-third took their first dose in the last week of life, and nearly two-thirds within a month of death. Of the complications certified coma was the most common (46 per cent.). Arteriosclerosis was reported in 24·8 per cent., chronic nephritis in 23·4 per cent., and gangrene in 23·4 per cent. In a series of 58 cases where no other complication than coma was present 21 received not a single dose of insulin.

Mortality-rates in 1924.

The 15,000,000 policy-holders of the Metropolitan Life Insurance Company provide a convenient albeit a selected group of the nation from which the trend of death-rates may be rapidly determined. Among this selected group the death-rate from diabetes in the first six months of 1924 shows a decrease of 21·6 per cent. among white policy-holders and more than 10 per cent. among coloured policy-holders, as compared with the four years preceding. The death-rate from automobile accidents was one of the few which showed increase—to 12·6 per 100,000 for whites and 11·7 for coloured. The coloured rate is a 92 per cent. increase over that for the corresponding period in 1922. Satisfactory declines are shown in the rates for diphtheria and typhoid fever. There is also a definite fall in the cancer rate for white policy-holders (72·3 to 68·7). The gain is nearly offset by a rise in the coloured rate. This situation is one that might be expected to arise if the educational programme is resulting in earlier diagnosis among the more intelligent people.

Anthrax in New York.

A clinical and epidemiological study of anthrax in the City of New York has recently been made by Dr. William Jacobsohn for the five-year period 1919–1923. He visited each one of the 61 reported cases. The infection in 32 of these was derived from shaving-brushes. One-third of all the cases occurred among brush-makers, warehousemen, truckmen, and longshoremen. The use of anti-anthrax serum alone gave as good results as any other method of treatment. Of 36 cases that received this treatment 29 recovered, although the fatality-rate for the 61 cases was 31 per cent. The causes contributory to fatality are classified as (1) virulence of infection, (2) extreme age or poor physique of patient, (3) delay in seeking medical attention, and (4) erroneous or late diagnosis and late treatment. The incubation period (from exposure to local swelling following the appearance of a papule) is given as follows: In 31 cases, one day; in six cases, two days; in four cases, three days; in five cases, four days; in five cases, five days; in one case each, six days, seven days, and eight days, respectively; and in seven cases undetermined. Sixty per cent. of the cases experienced no pain. In only 18 cases did the temperature rise above 102° F. As a consequence of active measures by the department of health, the incidence of anthrax in New York is declining rapidly. Only one case has been reported in the first six months of this year.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Fewer School-children in Vienna.

WHEN the secondary schools opened for the winter term in the middle of September the total number of new pupils showed a diminution on the figure for the previous year. Education is compulsory between the ages of 6 and 14 years, and not more than 11,000 children aged 6 years were enrolled, in comparison to last year's figure of 12,680. Consequently a number of schools had to be closed down. This falling-off in the numbers of school-children is one of the visible results of the decreasing birth-rate which has been recorded since the beginning of the century, and which was aggravated by the ten years of war and its consequences. The calculations based on the statistical data published by the Municipal Board of Health show that this year will probably be the last one in which a decrease will be manifest; the next school year will most probably give indication of a slight increase. But as the increase forecasted to the year 1928 is more than counter-balanced by the loss of numbers due to older pupils leaving the schools, the total number of children in school (which in 1923 was 146,200 boys and girls) will diminish to 119,000 in 1928. As a result of the constant falling-off of pupils there has been a very favourable decrease in the average number of children occupying one class-room. The average number is now 29–30 as compared to 50–70 in former years. This is an advantage from the sanitary and the social points of view. In classes for mentally affected children the number has been reduced to 12–18 pupils.

The Winter Session of the Vienna University.

The University of Vienna opened its gates to students in October, and the session closes in March, 1925. Whilst the number of medical students during the summer term was 2048, or about 30 per cent. of the total matriculated students at the University, 2342 have been enrolled for the winter session. This is the first year that the regular courses in all branches will be held just as before the war. A large number of classes will be given in the English language, as the American Medical Association of Vienna has arranged with the leading professors and assistants of the clinics and hospitals to hold special classes for their members. The fees vary between 4*s.* and 8*s.* per hour per student, not more than 10 being admitted to any one class; all English-speaking doctors may attend these classes. Apart from the regular clinical lectures on surgery, materia medica, dermatology, gynæcology, pediatrics, and ophthalmology, there has been arranged a variety of special lectures on such subjects as chemistry of the blood, diabetes, tuberculosis, social medicine, occupational diseases, psycho-analysis, and bacteriological and serological problems. One subject only will be more limited in its scope than in previous years—namely, anatomical dissections. Owing to the scarcity of cadavera (on which I reported some time ago), Prof. Tandler will not take up his regular anatomical lectures this year.

The Medical Profession and the Problem of Artificial Abortion.

The aspect of eugenics which aims at preventing undesirable births is now a leading issue in Austria. All classes of the population have come to understand that there are moral, social, medical, and even financial indications for the premature interruption of a pregnancy. The law, however, still sets its face sternly against this practice, and its action in certain cases in the last few months (vide THE LANCET, 1924, i., 1285) raised a violent protest from the medical profession and furthered the attempt to alter the existing law by amendments to a Bill before the National Assembly. The profession as a whole has openly taken up the fight against what I consider to be antiquated laws, and hardly a week passes in which the subject is not dealt with at mass meetings or in articles in the press or in petitions to the National Assembly and Ministry of Justice. No doctor now complies with the order of the Public Prosecutor, which demands that every case of abortion be notified to the police, nor do the hospitals, as a rule, make a diagnosis of abortion except where fatal results are expected.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. W. N. Blatchford is placed on the Ret. List.

ROYAL ARMY MEDICAL CORPS.

Maj. F. A. H. Clarke to be Lt.-Col., vice Lt.-Col. J. H. R. Bond, to ret. pay.

Maj. T. C. R. Archer is secd. for serv. under the Colonial Office.

Capt. W. H. Ferguson is granted the temp. rank of Maj. whilst empld. as Dep. Asst. Dir. of Pathology.

Capt. F. J. Hallinan relinquishes the actg. rank of Maj. on ceasing to be empld. as Dep. Asst. Dir. of Pathology.

Capt. H. W. L. Allott retires, receiving a gratuity.

TERRITORIAL ARMY.

Maj. V. T. Carruthers to be Lt.-Col. and to command the 137th (North Midland) Field Ambulance.

Maj. (Prov.) G. B. Brand resigns his commn. and retains the rank of Capt.

Lt. W. J. C. Watt to be Capt.

ROYAL AIR FORCE.

A. Harvey and H. W. D. Mackenzie (for duty at Royal Infirmary, Edinburgh) are granted short service commissions as Flying Officers.

INDIAN MEDICAL SERVICE.

Lt. A. L. Watts to be Capt.

Capts. Pappu Subbaramayya, A. Williams (and is permitted to retain the rank of Capt.), and Lt. Manohar Datta Gautama relinquish their tempy. commns.

The King has approved the retirement of Maj.-Gen. J. Jackson.

Gurbaksh Singh Chawla to be tempy. Lt.

GENERAL MEDICAL COUNCIL:
ELECTION OF DIRECT REPRESENTATIVES.

ENGLAND AND WALES.

FOUR names were selected last July by English and Welsh deputies at the annual meeting of the British Medical Association for nomination on behalf of the Association as Direct Representatives of the registered medical practitioners of England and Wales on the General Medical Council. These were Dr. R. A. BOLAM, Dr. J. A. MACDONALD, Sir JENNER VERRALL, and Dr. H. B. BRACKENBURY. On their behalf the following election address has been circulated.

LADIES AND GENTLEMEN,

The election of four Direct Representatives for England and Wales to the General Medical Council will take place early in November.

In the deliberations of the Council and in the exercise of its statutory powers there is constant need for a knowledge, so far as it can be ascertained, of the collective view of the profession.

We appeal as a group to you, the electors, in the belief that our conjoined experience and opportunities are of such nature as to enable us to offer you service which would be of value in this respect. Individually and as a group we have had in different capacities a considerable experience of varying professional duties and responsibilities, and we confidently claim an intimate knowledge of public medical work. Two of us (Dr. Macdonald and Sir Jenner Verrall) have been familiar with the work of the General Medical Council for a number of years and have the privilege at present of acting on some of the Committees of the Council whose activities have a very direct and practical bearing on the interests of the profession. Dr. Bolam has been one of your Representatives for the years 1919 to 1924. The record of public service and the very special knowledge of certain aspects of medical work possessed by Dr. Brackenbury are well known to the profession and will, we believe, commend his candidature to you.

One of the chief pre-occupations of the General Medical Council is with medical education, and it is important that matters relating thereto which bear upon the ultimate efficiency and interests of the practitioner should be adequately voiced by Representatives in direct touch with medical practice in its several branches.

The Council is now constantly consulted by the Government Department in Bills affecting the profession and in regulations proposed under Acts of Parliament.

Possible developments and extensions of a National Health Insurance Service are the subject of investigation by a Royal Commission now beginning its deliberations, and the effect of its findings on the whole life and outlook of the profession may be far-reaching.

The introduction of National Health Insurance has raised new ethical and disciplinary questions which have required the attention of the Council. Further developments may be expected to create fresh problems of a like nature on which your Representatives should be able to express practical and well-informed opinions.

We believe that there is more than ever a need for Direct Representatives on the General Medical Council who are experienced in administration and in the medico-political difficulties of the profession. We offer the assurance of a sincere desire to spare no effort in our power for the credit and welfare of the profession, should you honour us by electing us as your Representatives; and we ask not only for your vote but for your active assistance in securing the votes of your colleagues to this end.

R. A. BOLAM,
Representative Member, General Medical Council: Member, Voluntary Hospitals Commission: Member, Consultative Council of Ministry of Health on Medical and Allied Services: Chairman of Council, British Medical Association.

H. B. BRACKENBURY,
Chairman of Representative Body and of the Insurance Acts Committee of the British Medical Association: Vice-President, formerly President of the Association of Education Committees.

J. A. MACDONALD,
Representative Member, General Medical Council: Member Consultative Council of the Ministry of Health on Medical and Allied Services; formerly Chairman of Representative Meetings and Chairman of Council, British Medical Association.

T. JENNER VERRALL,
Representative Member, General Medical Council: late Chairman, Central Medical War Committee for England and Wales: Member of Council and formerly Chairman of Representative Meetings British Medical Association.

Oct. 23rd.

Dr. F. H. WESTMACOTT, of Manchester, who is standing as an independent candidate, presents to the electors a summary of his professional record. Qualifications: B.Sc. Vict., M.R.C.S., L.R.C.P. 1890, F.R.C.S. by examination 1894. He studied at Manchester University and afterwards in Paris and Vienna for about 18 months to acquire methods of teaching and practice. Since 1898 he has held appointments on the hon. medical staff of several hospitals, particularly the Manchester Royal Infirmary, where he is hon. aurist and laryngologist. He is University lecturer as well as examiner in oto-laryngology. His election address continues: "As consulting surgeon and teacher I have acquired a wide experience of the requirements of medical students and of medical education as well as of the needs of the public. In conducting post-graduate courses of lectures the question of qualifying diplomas in special branches of medicine and surgery has been of great interest to me. I am an examiner for the State Registration of Nurses. An appointment on the hon. staff of the Victoria Dental Hospital of Manchester for many years provided an intimate knowledge of the education and practice of dentistry. During the whole of my professional career I have taken an active interest in the energies of many medical societies, both scientific and ethical. Among other appointments I am a member of the North-Western Advisory Council of the Ministry of Pensions. Such vital questions as the National Health Insurance Acts and the Workmen's Compensation Acts have long engaged my attention. An intimate knowledge of them has convinced me that considerable amendment and improvement are necessary to obtain the maximum benefit and satisfaction to the public and the medical profession. The requirements of the medical services of the Army have impressed me during the 26 years I have held a commission in the auxiliary and regular forces."

Dr. Westmacott served from August 5th, 1914, to Jan. 29th, 1920, spending nearly three years in France in command of a general hospital, and later as A.D.M.S. of the Marseilles Base. Before going to France he commanded the 2nd Western General Hospital in Manchester. Since the war he has held the position of A.D.M.S. of the 42nd (East Lancs) Division, holding the rank of Colonel A.M.S. (T.). He is a Commander of the Order of the British Empire, a Knight of Grace of the Order of St. John of Jerusalem, and a Deputy Lieutenant for the County Palatine of Lancaster.

Dr. JOHN BROWN, who stood in 1919 as an independent candidate, writes that while he is not standing this time he still wishes to protest against the nomination by the British Medical Association of four Representatives, on the ground that this practically excludes the free election by the medical profession of Representatives who are not members of the Association. He advocates the division of the English constituency into four for electoral purposes.

SCOTLAND.

On behalf of the candidature of Sir NORMAN WALKER we have received the following letter.

SIR,—The President of the General Medical Council has issued his notice for the election to the Council of a Direct Representative of the Registered Medical Practitioners of Scotland.

We have ascertained that Sir Norman Walker, the present Representative, is willing again to place his services at their disposal. Sir Norman has made for himself a position upon the Council upon which those who have supported him in his previous candidatures may look with some pride. He is Chairman of the Business and Examination Committees, and a member of the Executive and Penal Cases Committees, while his selection by the General Council as Commissioner to India to investigate the conditions of Medical Education there speaks well for the position he has acquired in the esteem of the Council. We venture to express the opinion that our medical brethren in Scotland could not do better than support his candidature for another term of office.

We are, yours &c.,

MENTAL HOSPITALS SERVICE.

A SATISFACTORY year's work and several changes of interest are recorded in the annual report of the *Dorset Mental Hospital* for 1923–24. The recovery-rate has been high, 39 per cent. on total admissions and 54 per cent. reckoned on total recoverable cases. Satisfaction is expressed with the results of the "open door" system adopted in certain wards; the patients are also better classified, 84 are allowed parole within or outside the grounds, and 17 patients away on trial have received money allowances. Remarkably few epileptics and general paralytics have been admitted; the comparative freedom from syphilis of rural areas is doubtless the explanation in the latter case, but the rarity of epilepsy in Dorset is less readily explicable and is deserving of investigation. There is now an out-patient centre in Dorchester, conducted by the medical superintendent, Dr. G. E. Peachell, where 52 patients have been seen during its first year of working; 10 of these recovered, 12 were relieved, and 9 were certified and admitted to the hospital. In addition to a resident medical staff of four members, the hospital possesses a visiting dentist and a visiting physician, and has recently acquired a laboratory assistant (apparently not medically qualified), who has undertaken a large and varied amount of pathological work, including water analyses, serological and bacteriological work in connexion with typhoid and dysentery, and the preparation of vaccines. Among the causes of death appears one case of rupture of a coronary artery, surely worthy of note as an extremely rare occurrence.

The annual report of the *Brighton County Borough Mental Hospital, Haywards Heath*, for 1923 contains little but a bare record of changes among the patients, staff, and committee, apart from the observations made by a Visiting Commissioner, from which alone can any idea be obtained of the conditions under which the patients are living. His report embodies certain criticisms, some of which owe their origin to the fact that the fabric dates from 1859; the facilities, the lack of which is most severely felt, are a laboratory, clinical room, operating theatre, verandahs, baths, and an out-patient centre. It is also suggested that male patients should be shaved, that parole (with money allowance) should be granted more often, and that clothing and diet should be improved in certain respects. It appears that the ordinary patients' milk is skimmed to provide butter for debilitated cases; meanwhile, the nursing and domestic staff are supplied with margarine, but since they prefer to buy their own butter, their discarded margarine is melted down with dripping for th patients. This strange and complex proceeding would be humorous but for the fact that there are 21 known cases of active tuberculosis in the hospital Our resources in the treatment of mental disease are few enough, but we should surely use, at least in recoverable cases, those of which we have knowledge and among them an adequate dietary takes an important place.

Correspondence.

"Audi alteram partem."

CANCER AND SOME OF ITS SIGNIFICANT CHEMICAL REACTIONS.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Oct. 4th Mr. H. Gordon Reeves set out the salient features of the chemica work done on the cancer problem in the physiologica laboratory of King's College, London. There is a distinct parallelism between the work outlined and that initiated by Sir George T. Beatson in 1910 at the Glasgow Royal Cancer Hospital, and it is interesting to note that the work done in Glasgow during the last 10 or 15 years has received a large measure of confirmation from that of Shaw-Mackenzie and Reeves.

In Reeves's communication some points of an unsettled nature are brought forward, and I should like to draw attention to these. In the first instance Shaw-Mackenzie is quoted as stating that tissu lipolysis and utilisation of fats are defective in cancer In his opinion normal blood serum has an accelerating influence on lipoclastic activity, and this activit is diminished by the addition to lipase of serum from a cancerous subject. From this and other findings he concludes that there is a general deficiency in lipolytic control, which deficiency, we presume he considers is manifested in the carcinomatous locality. If this be so, then one would expect to find a lowered, rather than an increased, saturation in the fat of the adipose tissue affected. Instead Shaw-Mackenzie and Reeves have found, as we have in this research department, that there is an increase in unsaturation of the adipose tissue invaded by carcinoma. I do not think that the range of variation in lipolytic activity affects to any marked degree change in saturation. If anything, an increased activity in the tissues would increase the amount of free fatty acid. In a determination of iodine value this free fatty acid would be part of the lipin complex to be evaluated and its associates of glycerol or lecithin structural units would be absent from the ether extract. Thus to the complex there would be added a substance or substances with comparatively small molecules and a proportionately high unsaturation coefficient. As a result of such an addition due to increased lipolytic activity, the iodine value of the complex would manifestly be increased. It is on that teleological basis that we are inclined to question the validity of Shaw-Mackenzie's observation.

Recent research has shown that to simulate as closely as possible "in vivo" conditions the course of enzyme reactions must be controlled with due attention to the hydrogen-ion concentration. It is obvious, of course, that, in the test-tube, lipase activity is manifested by a change of pH towards the acid side, owing to an accumulation of the products of lipolysis. In the body, however, there is a delicately adjusted mechanism whereby the products of enzyme action are removed from the sphere of activity as soon as formed, and, because of this control, a constant level of hydrogen-ion concentration is maintained and enzymic inhibition is frustrated. It will be seen, then, that it is difficult to simulate the biotic courses of lipase activity in the test-tube and the interpretation of results becomes endowed with a misleading elasticity.

In the second place, Reeves's communication refers to the importance of such lipins as lecithin and cholesterol. It is fairly well established that there is an excess of lecithin in the cancer cell and that there is also a high cholesterol concentration. Reeves states that the increased iodine value observed in the fat of tumours is probably due in no small part to increased cholesterol content. I do not think that cholesterol would have any marked influence in the direction of unsaturation change. For example, if dioleopalmitin with a molecular weight of 858 and an iodine value of 59·2 have added to it a gram-molecular equivalent of cholesterol the rise in iodine value is 2·0. If, instead, lecithin be added in the same proportion, there is a rise of 1·9 units; if triolein be added, there is a rise of 13·7 units; if oleic acid be added, there is a rise of 7·6 units. In these computations lecithin, for the purpose of the argument, is taken to be dioleolecithin, although, like kephalin, it is generally assumed to have both a saturated and an unsaturated fatty acid in its molecule. If to a gram-molecular equivalent of triolein with a molecular weight of 884 and an iodine value of 86·2 a gram-molecular equivalent of dioleolecithin with an iodine value of 63·2 be added, then there is a depression of 11 units in iodine value. Under similar conditions, with cholesterol, the depression is 6·2. From these figures it will be seen that cholesterol and lecithin exert very little influence on saturation change, even though they have been associated in my calculation with neutral fat in such large proportions. Thus, in the case cited by Reeves, where Wacker has found a 66 per cent. increase in cholesterol, the increase in iodine value of an aliquot portion of the fat from this tissue would be in the neighbourhood of 1·3.

Dioleopalmitin and dioleostearin each give iodine values closely approximating to that of the fat of normal adipose tissue. In cancer, however, the minimum values of invaded fat is in the neighbourhood of 65. If, as the result of certain pathological processes, there is an increased accession to the fat of such lipins as cholesterol and lecithin, there is practically no change in the iodine value of the fat provided the original value is near the cholesterol and lecithin values—65·8 and 63·2. If, however, the original iodine value of the cancerous fat is in the neighbourhood of 70 (the common figure found in our research work) then a marked increase of these two accessory lipins would produce a depression rather than a rise in the iodine unitage. This is demonstrable by a single hypothetical example. If triolein and lecithin are mixed in gram-molecular equivalents, there is a depression in the iodine value of triolein of 11 units. It would seem then that the threshold iodine value of fat change—i.e., the level at which it is liable to change in saturation from the addition of lecithin and cholesterol—is well under 65, and approximates to the level of the normal. The rôle of these lipins in influencing saturation change in cancer is, therefore, negligible, although it is conceivable that lecithin more than cholesterol, in virtue of its potentiality of lecitholytic change with the production of free oleic acid, might influence saturation change. Oleic acid added to dioleopalmitin (gram-molecular equivalents) produces a rise in iodine value of 7·6 units. It is quite obvious that in the tissues the amount of free oleic acid would not be so high as this relative to the amount of neutral fat, and it seems feasible to postulate that the major factor concerned in giving the high unsaturation index so characteristic of the fats in cancer is an oxidase mechanism whose main sphere of operation is confined to the fatty acid constituent of the fat or lipin molecule.

Reeves finds a distinct hypercholesterolemia associated with malignant disease. Work on the cholesterol content of the blood has been carried out at the Glasgow Cancer Hospital for over a period of a year, and a paper embodying the findings will shortly be published in the *British Journal of Experimental Pathology*. In the main, the results found indicated a slight hypocholesterolemia, although in view of the conflicting literature on the cholesterol of the blood it is difficult to establish a condition either of hyper- of hypo-cholesterolemia. In the literature consulted, four or five different "normal" cholesterol values ranging from 0·09 per cent. to 0·25 per cent. are given for the cholesterol concentration in serum. In the paper referred to above, there is a description of a uniform technique for the estimation of this substance. Seventy cases were evaluated and it was found that a seasonal rhythm existed in cholesterol concentration, so that the "normal" figures already referred to were included in the range. This concentration rhythm extended to normal cases, and a comparison of these with malignant cases gave an indication of a slight decrease in the percentage content of cholesterol.

One would naturally expect a hypercholesterolemia, since autolytic change in tumour areas is bound to flood the tumour tissue with cholesterol which is an inert compound, easily thrown out of tissue-coördination, because of its insolubility and low reactivity, but it seems that the blood uptake of this substance is counterbalanced by its absorption by the tumour mass. I am, Sir, yours faithfully,

ARCHIBALD N. CURRIE, M.A., B.Sc., A.I.C., F.C.S.,
Biochemist, Research Department, Glasgow Royal Cancer Hospital.
Oct. 22nd, 1924.

ERYTHEMA NODOSUM.

To the Editor of THE LANCET.

SIR,—I should be grateful if any practitioner among your readers who has met with cases of erythema nodosum in endemic or epidemic form, or has seen examples of the infectious nature of this disease, would communicate with me on the subject.

I am, Sir, yours faithfully,
G. F. WALKER, M.B., Ch.B.
General Infirmary, Leeds, Oct. 27th, 1924.

FACT AND THEORY IN RADIOTHERAPY.

To the Editor of THE LANCET.

SIR,—Prof. Russ is aggrieved because I said "One cannot 'lift' the results obtained by experiments on animals and apply them forthwith to the human subject." Now, to lift and apply forthwith means, if it means anything, to repeat, *without modification*, the procedures applied to the animal, and to expect, in man, precisely the same results as were obtained in the animal. I submit that we are not so closely related to cavies and conies, not to speak of representatives of the genus *mus*, that experimental results may be so applied to us. And I shall be much surprised if anyone actually engaged in the practice of medicine holds a different view. To say this is not in any way to deprecate the value of such experiments.

I am, Sir, yours faithfully,
F. HERNAMAN-JOHNSON.
Harley-street, W., Oct. 27th, 1924.

THE LATENT INTERVAL IN FUR DERMATITIS.

To the Editor of THE LANCET.

SIR,—All who have had special experience in dermatology will agree with the general conclusion stated in the last sentence of the excellent memorandum[1] issued recently by Dr. A. C. Parsons, in which he says, "Defective or careless technique or the use of potentially dangerous dyes is, therefore, in all probability the cause of the fur dermatitis in the circumstances under consideration." There is one elusive point, however, that deserves comment. The rash in its early stages is of a papulo-erythematous type, and results from the application of an external irritant. In some cases it follows shortly after exposure, just as it would follow the application, say, of mustard or of cantharides. The report, however, states that in most patients there is a latent interval varying from two to six weeks or more. Why this assumption of latency over so long a period? One would not expect the effects of a mustard leaf to be delayed for six weeks "or more." On what principle is this assumption of delayed action to be explained in the case of the incriminated fur?

---

[1] THE LANCET, Sept. 6th, p. 505.

Various fallacies have already been indicated by Dr. Parsons. Since answering his official circular letter asking for information I have made a further observation that appears to point to an additional pitfall, as follows. For a long time I had been puzzled, as many others must have been puzzled, by the frequent answer made by patients, when told that their skin trouble was due to a fur, that it could not possibly be due to the fur, for it had been worn the previous winter, and had caused no rash. The fallacy of this dawned upon me one day when I noticed that the fur at the edge of the collar had been worn away and flattened down so that the patient's neck came into contact with the hide as apart from the actual hair; this altered condition probably explained both present susceptibility and former immunity. When we consider the structural difference between the fur and the underlying hide it becomes reasonably clear that the chemical irritant presumably concerned in most cases of fur dermatitis would be much more likely to be retained in the hide than in the hairs. Ergo, while a fur collar is new and the hair intact the neck of the wearer does not come into contact with the irritant accumulated in the hide, whereas when the hair is displaced or worn away the skin presses against the saturated hide, and dermatitis is the result.

This explanation avoids the assumption of a latency in these cases that is not in accordance with general dermatological experience.

I am, Sir, yours faithfully,

London, W., Oct. 27th, 1924. DAVID WALSH.

INTRA-OCULAR TENSION IN MYOPIA.

To the Editor of THE LANCET.

SIR,—I venture to state that few, if any, ophthalmic surgeons accept Dr. Edridge-Green's theory of the production of myopia. All the organs of the body vary in size in different individuals, and if we are to attribute the large or myopic eyeball to a pathological mechanism, then to what are we to attribute the more prevalent small, or hypermetropic, eyeball? It is accepted that myopia is commoner among schoolgirls than boys, and it was so long before gymnastics were introduced into schools. Sixty per cent. of myopic scholars are girls. Artificial myopia, or myopia due to spasm of accommodation, does "diminish or become emmetropic," but true static or ordinary myopia probably never disappears. The size of the eyeball is, in my opinion, determined by the factor of heredity. There are some exceptions to this finding. About 10 per cent. of myopes have corneal opacities, the result of keratitis. In this disease it is probable that toxins pass through the cornea and filter back along the coats of the eyeball, causing softening, and, later, stretching, at the sclero-corneal junction, or at the posterior segment of the eyeball.

I am, Sir, yours faithfully,

Cambuslang, Oct. 25th, 1924. J. A. WILSON.

AUTO-HÆMAGGLUTINATION IN PERNICIOUS ANÆMIA.

To the Editor of THE LANCET.

SIR,—I have read with great interest the article on this subject by Dr. H. Cohen and Dr. A. Roby Jones in your issue of Oct. 25th. Auto-agglutination of the red blood corpuscles is a phenomenon which occurs comparatively frequently in certain tropical fevers—notably trypanosomiasis. So frequently has it been observed in this disease, that at one time it was even suggested that the phenomenon of auto-agglutination in a thick drop was diagnostic of trypanosome infection. It is not invariably so; but it is highly suggestive. During the last three years I have had two cases of trypanosomiasis in which auto-agglutination occurred and prompted me to search a blood-film further for trypanosomes with ultimate success.

1. A patient consulted me in June, 1922, on his return from N. Rhodesia, where he had been treated for trypanosomiasis marked auto-agglutination of his red blood corpuscles was observed, and prolonged search revealed *Trypanosoma rhodesiense* from which infection he died six months later.

2. A Government official from the Gambia consulted me in June, 1924, complaining of general weakness and malaise. Marked auto-agglutination of his red blood corpuscles was present, and further search revealed comparatively numerous *Trypanosoma gambiense*. Since that date he has been vigorously treated with "Bayer 205" and tryparsamide with the result that he is now in normal and excellent health. When seen in October the auto-agglutination phenomenon was still observed, though there are now no signs of anæmia and his blood count and hæmoglobin percentage are normal.

3. A very anæmic clerk from the Gold Coast consulted me on Oct. 14th; his spleen was enlarged. The diagnosis rested between subtertian malaria and trypanosomiasis. Marked auto-agglutination of his red blood corpuscles was present, while numerous subtertian malaria parasites were found. He has now almost entirely recovered, though the auto-agglutination phenomenon is still present.

It therefore appears that the phenomenon is of practical diagnostic importance in tropical fevers and from the evidence in the second case I have cited it does not necessarily appear to be associated with any ascertainable anæmia.

I am, Sir, yours faithfully,

London, W., Oct. 25th, 1924. PHILIP MANSON-BAHR.

DENTAL DRESSERS.

To the Editor of THE LANCET.

SIR,—Dr. Kerr states that "there are about 5000 names on the Dental Register of whom about 3000 are fully trained." If he will examine the Dentists Register for 1924 he will find that it contains the names of 13,473 dentists, of whom 6172 are fully qualified dental surgeons. The date of the report of Sir George Newman on which Dr. Kerr bases his imaginary "shortage of dentists" is the year 1920. Is it possible that Dr. Kerr is unaware of all that has happened in the dental world since then? I can assure Dr. Kerr, and I speak from intimate knowledge of the facts, that there is no shortage of fully qualified dentists for any necessary extension of the school dental service. The numbers applying for every such appointment give sufficient proof of that. When Dr. Kerr speaks of the work done by dental hygienists in America, is he aware of the difference between the work done by these persons and that at present done by dental dressers in Derbyshire?

I am, Sir, yours faithfully,

ROBERT LINDSAY.

Dental Secretary, British Dental Association.

Russell-square, London, W.C., Oct. 27th, 1924.

*** We note that the Dental Board on Oct. 7th received a communication from the Derby county medical officer of health in connexion with the sanction of the Minister of Health to the employment of three trained dental dressers on minor dental work under the personal supervision of a registered dentist for the treatment of children under school age. The Maternity and Child Welfare Committee of the county expressed itself as satisfied if the dentist was allowed to supervise the work of only one dental nurse working at the same time as himself, provided that the work which the dental nurses were allowed to do included (*a*) examinations with probe and mirror; (*b*) extractions and treatment of temporary teeth; and (*c*) treatment of the first permanent molars. The Board, however, resolved to adhere to the recommendations of the previous Board in regard to this matter.—ED. L.

Obituary.

WILLIAM HENRY B. AIKINS, M.D. TORONTO, L.R.C.P. LOND.

Dr. W. H. B. Aikins, consulting physician to the Toronto General Hospital and a well-known Canadian authority on cancer, died suddenly from angina pectoris while at his consulting rooms in Toronto on Oct. 3rd, in his sixty-sixth year. A son of the late Hon. J. C. Aikins, he was born in the Peel County and was educated at Upper Canada College. In 1881 he graduated in medicine from the University of Toronto, and in the same year came to England and obtained his L.R.C.P. Lond. After doing post-graduate work in New York, Edinburgh, and Vienna, he entered into practice at Toronto in 1884, where he acquired a large consulting connexion and became an outstanding figure in the Toronto medical world. A keen student of his profession and quick to take advantage of scientific advance in treatment, he was one of the first of his colleagues to use radium. He organised the American Radium Society, of which he was one of the first presidents. For many years he was physician to the General Hospital, Toronto, and was on the consulting staff at the time of his death. At one time he was consulting physician to the Toronto Hospital for Incurables and the King Edward Sanatorium, with which latter institution he was connected for some 10 years. Dr. Aikins was a prominent figure in many medical societies; he held the office of president of the Toronto Clinical Society and had a guiding hand in the Ontario Medical Association, the British Medical Association, and the Mississippi Valley Association. In 1907 he was elected as vice-president of the Canadian Medical Association, and for 15 years he acted as Senator of the Toronto University, representing the medical graduates. Dr. Aikins took a keen and active interest in international medical problems. In 1909 he was secretary for Canada at the International Medical Congress in Budapest, while in 1916 he held a similar office at the Lisbon Congress. He was a Fellow of the Canadian College of Physicians and a member of the Royal Canadian Institute in London. Well known as one of the proprietors and editors of *The Canadian Practitioner*, Dr. Aikins made many contributions to medical literature and was the author of the "Radium Treatment of Rodent Ulcer, Cancer, and Keloid" which was published in 1910. He was a prominent Freemason.

Dr. Aikins made many professional friends both in England and abroad, and his advice was keenly sought by—and freely given to—his young professional colleagues in all countries. He married in 1887 Augusta, daughter of the late Dr. Easton Hawkesworth, who survives him.

NATHANIEL THOMAS BREWIS, M.B., C.M., F.R.C.P. & S. EDIN.

WITH the death of Dr. N. T. Brewis at his house in Drumsheugh-gardens, Edinburgh, on Oct. 21st, in his sixty-ninth year, the Edinburgh Medical School loses a well-known gynæcological surgeon and a popular teacher.

Nathaniel Thomas Brewis was born at Eshott Hall, Northumberland, in 1856, was educated at the Edinburgh Institution and Edinburgh University, graduating M.B., Ch.M. in 1882, after which he held posts as house surgeon in the Royal Infirmary of Edinburgh and the Glasgow Maternity Hospital. In 1886 he became a Member of the Royal College of Physicians of Edinburgh, and was elected to the Fellowship in the following year; in 1899 he was elected a Fellow of the Royal College of Surgeons of Edinburgh. Early in his career he became interested in diseases of women and specialised in this branch. He confined his work entirely to gynæcology and developed a large private practice. The special features of his operative work were his careful technique, his striking dexterity, and the marked deliberateness with which every detail was performed. For a great number of years Dr. Brewis was associated with the gynæcological wards of the Royal Infirmary of Edinburgh, first as clinical assistant and assistant surgeon, and subsequently as gynæcologist in charge. He was lecturer and examiner to the University and the Royal College; he was ever a popular lecturer and will be remembered by his students both as a careful teacher and a sympathetic examiner. Formerly he held the post of gynæcologist to Leith Hospital, and to the time of his death occupied the post of gynæcologist to the New Town Dispensary. Everything was well arranged to the last detail at the nursing home in Cambridge-street, with which he was closely connected for a great number of years. He was the author of "Outlines of Gynæcological Diagnosis," and also contributed the article in the Encyclopædia Medica on "Displacements of the Uterus." The bulk of his writings, however, are to be found in the Transactions of the Obstetrical Society of Edinburgh of which he was at one time president. Among these are "A Series of Abdominal Sections," "Some Renal Cases," "Case of Pregnancy Complicated by Fibroid Tumours and Treated by Hysterectomy," and "Six Cases of Vaginal Cæsarean Section." He was a Fellow of the British Gynæcological Society, the Medico-Chirurgical Society of Edinburgh, and the Royal Medical Society of Edinburgh.

Brewis was keenly interested in Rugby football; in early days he played for his school, and later was one of the founders of the Edinburgh Institution Former Pupils Football Club. As a student at the University he represented Scotland on six occasions, in 1876 and 1878 against England, and in 1879 and 1880 against England and Ireland. He always maintained his interest in the game, and was at one time president of the Scottish Rugby Football Union.

During the last few years of his life, in fact from the time of his retirement from the Royal Infirmary, his health had not been good, and lately he had been able to do very little. He was twice married, and is survived by his widow, a son, and a daughter.

Medical News.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Oct. 22nd, the Vice-Chancellor (Prof. E. A. Gardner, Litt.D.) being in the chair, a University chair of anatomy tenable at the Middlesex Hospital Medical School was instituted as the result of a munificent gift of £20,000 by Mr. S. A. Courtauld. The title of the chair will be "The S. A. Courtauld Chair of Anatomy," and Dr. Thomas Yeates, at present University professor of anatomy at the School, was appointed as the first occupant.

UNIVERSITY OF GLASGOW.—At the graduation ceremonial on Oct. 20th the following degrees were conferred:—

M.D.—George A. Allan (with honours), Andrew Climie (with commendation), John A. Doctor, Alexander H. Hall, and William L. Templeton.

M.B., Ch.B.—With honours: Gavin M'Callum. With commendation: Edgar A. Underwood, John C. D. Mitchell, George G. Macphee, William Mackay, and John Hamilton. James A. Adie, Archibald D. P. Alexander, John L. Allan, Ruth M. Allinson, Christina M. Anderson, James A. Barrie, Jessie L. Barrie, John B. Bennett, James Boyd, William Brackenridge, Francis H. Brisby, James B. P. Brown, James Buchanan, John A. Buchanan, Joseph Byers, Allison W. Cameron, Donald E. Cameron, David H. Campbell, Peter Campbell, Margaret E. Chalmers, James H. Chisholm, George Christie, James C. Clark, Ellen M. Clow, George A. Cormack, Annie T. Crookes, James T. Curran, William Cuthbertson, Joseph J. B. Dias, Robert Dick, Alfred T. B. Dickson, Enid M. Dixon, Alexander C. Douglas, Margaret C. Douglas, Robert Drummond, James M. Duff, Alexander Dunlop, Annie K. Easson, Ronald C. Fergus, John Ferguson, Joseph E. Fisher, James Flind, Margaret S. Ford, Robert D. Forrest, Thomas E. Gilchrist, William Glasgow, Mary S. Glen, Robert M. Gordon, George G. Graham, Thomas F. Greenhill, Grant R. Gribben, James Hamilton, John N. Hamilton, Isabella M. Harkness, Archibald C. Holms, Esther S. Hood, Jean F. Howie, Andrew B. H. Irvine, Helena J. S. Irving, William C. Jack, Elinor D. Jackson, John Johnston, John A. Ll. V. Jones, John Kyle, Robert L. Leask, Douglas M. Leroux, Beryl P. Lye, Mungo M. M'Clelland, Elizabeth L. M'Corquodale, Dhul A. M'Cowan, Robert M'Cracken, Thomas M'Culloch, Robert K. M'Dougall, Hugh A. G. MacEwen, Malcolm MacEwen, Daniel M'Farlane, Josephine M. Macfarlane, John Macfie, William J. M'Intosh, Christian W. F. MacKay, Ian A. Mackay, John Mackay, William Mackay, Alexander R. M'Kelvie, William MacKenzie, Murdo Maclean, Neil M'Lean, Alexander J. Macleod, Coinneach B. Macleod, James M'Whirter, Elizabeth M. S. Meek, Gavin Millar, Hugh V. R. Miller, Patrick J. Molloy, James A. Montgomery, Edward J. Morgan, Robert R. Morrison, Christian D. F. Morton, Robert Morton, Walter D. Muir, William P. Muir, Margaret K. Murray, James Myles, Samuel M. Newman, Alexander Nicolson, Archibald Ogg, Tsoh-Chen Pan, William Parker, John Petrie, Alexander M. Pollock, Alexander D. M. Pyle, John Pyle, John A. C. Randall, Dorothy E. D. Rankin, Mary A. Rigby, Peter M. Ritchie, Edith M. Roberts, Graham M. Robertson, Harold C. Robertson, Helen I. Robertson, Andrew B. F. Rodger, Alfred R. Rooke, Alexander Rose, William Russell, Leslie G. Scoular, Peter M. Shepherd, Thomas R. Sinclair, Leo F. Skinnider, Isobel U. Sloan, Gilbert J. Smith, James K. S. Smith, Ian F. Somerville, Mary C. Stevenson, Mary S. Stevenson, Peter H. Stewart, John M. Stirling, Annie R. Stuart, Barbara S. Tulloch, George W. Vaughan, John G. Warnock, John Waters, Elizabeth M. Weir, Hamish M. Weir, John A. Wilson, and Frances D. Young.

Gavin M'Callum gains the Brunton Memorial Prize of £10 awarded to the most distinguished graduate in medicine of the year, and Elinor D. Jackson gains the West of Scotland R.A.M.C. Memorial Prize awarded to the candidate who obtained the highest aggregate marks in the Final Examinations held during the year 1924.

Royal Society of Medicine: Annual Dinner.—It has now been decided that private guests, including ladies, may be invited to the dinner on Nov. 26th, and that the tables are to be arranged so as to accommodate parties of friends and guests.

British Medical Association: Annual Council Dinner.—The third annual Council dinner of the British Medical Association was held in Edward VII. Rooms, Hotel Victoria, London, on Wednesday, Oct. 22nd, when Dr. R. A. Bolam, chairman of Council, presided. There was a large and distinguished attendance, including the Directors-General of the Naval and Army Medical Services, the President of the Royal College of Physicians, the newly elected President of the College of Physicians of Ireland, the Registrar-General, Sir Lister Scott, Lord Dawson of Penn, Sir Philip Magnus, Sir Henry Craik, and the Presidents of the various sister medical societies. The toast of "The Retiring Officers" was proposed by Dr. E. K. Le Fleming, who likened the retiring chairman of the Representative Body to the police officer on point duty at an important traffic centre borne down upon by omnibus resolutions and riders, but always able to direct the traffic safely and expeditiously. He spoke of the retiring President of the Association as one who had infected his colleagues with his genial personality, and who as host, city father, and friend of the poor, had greatly served his fellows. Mr. C. P. Childe, in replying, dwelt with pleasure on the fact that the holder of the office was necessarily one who held the confidence of his colleagues. Dr. Wallace Henry, in replying, recalled some of the important events in his three eventful years of chairmanship, when the constitution had been revised, a working agreement reached with the public health service, and affiliation completed with the Canadian Medical Association. The toast of "The Common Health" was proposed by Dr. H. B. Brackenbury, who recognised that it went far beyond the medical profession and its concerns. Were our towns well planned, every one given a proper house and smoke done away with, that would do more than the medical profession alone could do in many years. He hoped that more men and women would serve on public bodies and take their share in the common health. He objected to the distinction, now obsolete, between preventive and curative medicine. "Antenatal care and treatment is preventive midwifery; immediate post-natal care and treatment is preventive gynæcology." Education and health were but two aspects of the same thing. Sir George Newman, who responded, acknowledged the disinterested struggle of the Association to win and maintain the common health. He reminded the gathering of the tercentenary of Sydenham, who not only laid the foundation of medical practice but was himself practitioner and public servant in one. The National Insurance scheme he characterised as a concrete attempt to reduce the economic difficulties of the patient which prevented him from getting the full benefit of medical knowledge. The toast of "Our Guests" was proposed by Mr. N. Bishop Harman in a witty speech, to which response was made by Sir Arthur Robinson, First Secretary of the Ministry of Health, Sir StClair Thomson, President of the Royal Society of Medicine, and Dr. G. H. Simmons, late editor of the *Journal of the American Medical Association*. Dr. Simmons contrasted the problems of the American and British associations, and set out the enormous difficulties of distance with which the American Association had to cope. In spite of these it had grappled successfully with the great problem of medical education, in regard to which he gave some striking figures. Mr. H. S. Souttar proposed "The Chairman," who responded in a few well-chosen words. A pleasant programme of vocal and instrumental music filled up the gaps in a crowded evening.

St. Thomas's Hospital Old Students' Dinner.—About 160 old students of St. Thomas's and their guests were present at the dinner in the Princes Restaurant, Piccadilly, on Oct. 24th, at which Dr. Seymour Taylor occupied the chair. In proposing the toast of St. Thomas's Hospital and Medical School the chairman made an amusing speech and referred to the day he had visualised in dreams when it would be possible to perform a surgical operation for mitral stenosis. The toast was responded to by the treasurer of the hospital, the Hon. Sir Arthur Stanley, and by the Dean of the Medical School, Sir Cuthbert Wallace. Sir Cuthbert Wallace spoke feelingly of the loss the hospital had sustained through the death of Prof. S. G. Shattock, for many years curator of the museum, which was now called the Shattock Museum, and of Sir Archibald Reid, former radiologist to the hospital. Dr. Henry Gervis, who had died recently, had obtained his first appointment to the old hospital in the borough. During the year the King had conferred honours on three St. Thomas's men. In speaking of the present athletic record of the Medical School, the Dean remarked that although the students had not carried off the palm on the football field, St. Thomas's Hospital nurses had beaten Guy's Hospital nurses in the final of the Inter-hospitals tennis tournament. "The Chairman" was then proposed by Sir Cuthbert Wallace, and he gave a graphic description of how Dr. Seymour Taylor had taught him anatomy. Dr. Seymour Taylor replied. The visitors were welcomed by Sir George H. Makins, and Sir John Bland-Sutton also spoke. Among the guests were Dr. C. R. Box, Sir Charles Scott Sherrington, Sir William B. Leishman, Surgeon Vice-Admiral J. Chambers, Sir Charles A. Ballance, Sir Richard Havelock Charles, Sir Hector Mackenzie, Sir Seymour J. Sharkey, Dr. H. G. Turney, Mr. Percy Sargent, Mr. G. A. Maling, V.C., and Dr. Ingleby Oddie.

Chelsea Clinical Society: Annual Dinner.—This society held its annual dinner at the Café Royal on Oct. 21st. Dr. Gordon Lane, the President of the society, occupied the chair, and nearly 100 members and guests were present. Amongst the latter were the Presidents of the Medical Society of London, the Royal Society of Medicine, and the Hunterian Society, the Dean of the Cancer Hospital, the Officer Commanding the Royal Military Hospital, Millbank, and representatives of *The Lancet* and the *British Medical Journal*. In proposing the toast, "The Progress and Prosperity of the Chelsea Clinical Society," Sir StClair Thomson expressed enthusiasm for the work accomplished not only by the central societies, such as the Medical Society of London, but of their very vigorous grandchildren of which the Chelsea Society is a notable example. Dr. Lane, in reply, referred to the rapid progress of the Chelsea Society, which, with a history of only 28 years, is to-day in a more flourishing position and has a larger membership than ever before. A special feature of this society is the manner in which it brings the local practitioner into close association with the consultants, both branches having equal representation upon all its committees. Judicious management and the careful selection of the programme for each session has led to great popularity, especially with medical men who have recently embarked upon general practice, and it is especially towards these that the society extends a welcome. The President announced that the forthcoming programme of the society includes, besides clinical evenings, discussions on the maladies common to the four great periods of life: infancy, adolescence, the climacteric, and senility. Dr. Eric Pritchard, Dr. A. P. Beddard, Sir Thomas Parkinson, and Dr. Leonard Williams are to be the principal speakers at these meetings. The health of the guests and the President was drunk with acclamation, and some delightful singing by the Westminster Singers added to the enjoyment of the evening.

Fellowship of Medicine and Post-Graduate Medical Association.—A comprehensive course in venereal disease will be held at the London Lock Hospital (Dean-street) from Nov. 3rd–29th. The course will consist of clinical work every day in the wards and out-patient departments and a daily formal lecture on the different aspects of this disease. Also beginning on the same date is a month's course in dermatology at the St. John's Hospital for Diseases of the Skin. Demonstrations will be given in the various departments, including laboratory work, and, twice a week, lectures at 5 p.m. From Nov. 10th–22nd St. Mark's Hospital will hold a course in proctology comprising operations, demonstrations, and lectures by members of the staff. A course in gynæcology has been arranged by the Chelsea Hospital for Women from Nov. 21st to Dec. 6th. Clinical demonstrations and lectures will be given in the wards and out-patient department, together with operations and formal lectures. Full particulars of any of the foregoing courses will be sent on application to the Secretary of the Fellowship, 1, Wimpole-street, W.

Royal Dental Hospital of London.—A course eight post-graduate lectures will be delivered in the :hool of Dental Surgery at the hospital at 5 P.M., between ov. 19th and Jan. 23rd next. The lectures are open to 'actitioners, advanced students, and others interested in the ıbjects. Admission is free, without ticket.

Institute of Hygiene.—At the recent annual eneral meeting of the Institute at 33–34, Devonshire-street, ondon, W., the following office-bearers were elected: r Thomas Oliver to be President, in succession to the te Sir Malcolm Morris; Prof. John W. H. Eyre to be a ice-President: Dr. Soltau Fenwick, to be Chairman of the eneral Council; and Mr. Robert H. Elliot, F.R.C.S., to Vice-Chairman. Mr. Grant Ramsay, who founded the stitute of Hygiene 21 years ago, retired as Principal of ıe Institute at the end of last month.

Royal Southern Hospital, Liverpool.—A series rooms specially equipped for electro-therapeutic treatment ıd massage have been added to the orthopædic department this hospital. These were formally declared open by ord Derby on Oct. 24th as part of the commemoration of ıe jubilee of the hospital. Special features of the department include the apparatus for remedial exercises, baths, ıd arrangements for ionic medication. It is also intended form a school for the training of students in electroıerapeutics and medical gymnastics.

University of Leeds.—Dr. F. S. Fowweather has een appointed to the Lectureship in Chemical Pathology :cently instituted. Dr. Fowweather graduated with firstass honours in chemistry (first division) at Liverpool niversity in 1914, gaining the Isaac Roberts scholarship ıd the John Willox exhibition. After a year's research he as awarded the M.Sc. degree, and he is also a Fellow of the ıstitute of Chemistry. Later Dr. Fowweather took up the udy of medicine and graduated M.B., Ch.B. at Liverpool niversity in 1922, subsequently obtaining the Diploma in ublic Health. He has been in general practice in llesmere Port, and has had chemical experience in industry.

Cancer Research Prize.—The committee of the hristie Hospital, Manchester, offers a prize of £300 for ıncer research. Candidates must be qualified in medicine in science cognate to medicine and must submit evidence original research work bearing on cancer done and rojected, which shall in the opinion of the assessors qualify ım for the prize. The object of the prize is to support search work already in progress. The assessors will take to consideration promising work which might fail for ant of financial help. The successful candidate will be quired to send results of his work in a report ready for ublication, or to give a lecture in Manchester. The prize ill be awarded in two instalments. The competition is pen to research workers of any nationality provided that l documents are submitted in the English language. pplications must be sent to the Chairman of the Medical oard, Christie Hospital, Manchester, on or before Dec. 31st, 924. The decision of the assessors shall be final, and they ıall have power to divide or withhold the prize as they ıink fit.

NFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 18TH, 1924.

Notifications.—The following cases of infectious disease 'ere notified during the week, namely:—Small-pox, 80; :arlet fever, 2165; diphtheria, 1091; enteric fever, 104; neumonia, 698; puerperal fever, 52; cerebro-spinal fever, ; acute poliomyelitis, 28; acute polio-encephalitis, 12; ıcephalitis lethargica, 43; continued fever, 2; dysentery, ; ophthalmia neonatorum, 114. There were no cases of holera, plague, or typhus fever notified during the week. ine of the 12 cases of acute polio-encephalitis were notified :om Liverpool. The cases of small-pox were reported from he county of Chester, 1 (Dukinfield); Derbyshire, 12 Derby, 4; Bolsover, 1; Chesterfield, 2; Chesterfield R.D., 3; Clowne, 2); Lancaster, 17 (Ashton-under-Lyne, 1; Hurst, 6); Leicester, 7 (Melton Mowbray); Lincoln, 6 (Gainsborough); Northumberland, 7 (Ashington); otts, 3 (Mansfield, 2; Mansfield Woodhouse, 1); Warwick, (Nuneaton, 4; Meriden R.D., 1); Yorks N. Riding, 6 Middlesbrough, 5; Eston, 1); Yorks W. Riding, 6 Rotherham).

Two corrections are made in the return; the reported ›tals for encephalitis lethargica and continued fever for he week ended Oct. 11th should have been 44 and 10 respecively. A case of typhus fever shown for the week ended ›ct. 4th should have been a case of enteric fever.

Deaths.—In the aggregate of great towns, including London, here were 9 deaths from enteric fever, none from small-pox, from scarlet fever, 29 from diphtheria, 13 from measles, 4 from influenza. In London itself the diphtheria deaths umbered 14 and the deaths from infantile diarrhœa fell to 21.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Nov 4th.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Cases:
Mr. Paul Bernard Roth: (1) Cases of Torsion of the Tibia. (2) Case of Fracture Dislocation of Head of Radius.
Mr. Muirhead Little: Case of Neglected Injuries to both Knee-joints.
Cases will also be shown by Mr. Bristow and others.

PATHOLOGY: at 8.30 P.M.
Laboratory Meeting at the Inoculation Department, St. Mary's Hospital, Paddington.
Sir Almroth Wright: Some New Technique.
B. J. Collingwood: The Influence of Gravity on the Diffusion of Dissolved Carbon Dioxide.
J. Freeman: Protein Idiopathy Experiments.
R. M. Fry: Demonstration of the Proteolytic Properties of Hæmolytic Streptococci.
L. Colebrook: Enumeration of Bacteria in Blood in Septicæmia.
A. Compton: Demonstration of Blood-urea Estimation by Ambard's Apparatus.
Joan Ross: Staining of Actinomycosis Clubs.
W. D. Newcomb and Joan Ross: Demonstration of Pathological Specimens.
A. Fleming: A Simple Method of Removing Leucocytes from Blood.

Wednesday, Nov. 5th.

SURGERY: at 6 P.M.
Presidential Address:
Mr. H. J. Paterson: The Lure of the New.

Thursday, Nov. 6th.

OBSTETRICS AND GYNÆCOLOGY
EPIDEMIOLOGY AND STATE MEDICINE
SOCIETY OF MEDICAL OFFICERS OF HEALTH } at 8 P.M.
Joint Discussion on the Notification of Puerperal Sepsis.
The following have promised to speak:—
Dr. R. Dudfield and Dr. W. Butler, Section of Epidemiology and State Medicine; Dr. R. A. Lyster and Dr. J. Cates, Society of Medical Officers of Health; Dr. Herbert Williamson and Dr. J. S. Fairbairn, Section of Obstetrics and Gynæcology.

Friday, Nov. 7th.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases will be shown by Mr. C. Gill Carey, Mr. G. W. Dawson, Dr. E. W. Goodall, Sir James Dundas-Grant, Dr. Irwin Moore, Mr. E. Broughton Barnes, and others.

ANÆSTHETICS: at 8.30 P.M.
Paper:
Mr. F. T. G. Hobday: The Selection and Administration of Local and General Anæsthetics for Animals (with epidiascopic illustrations).

COMPARATIVE MEDICINE:
Members of the Section of Comparative Medicine are specially invited to attend this Meeting.

Saturday, Nov. 8th.

OTOLOGY: at 10 A.M. (Cases at 9.15 A.M.)
Presidential Address:
Dr. J. Kerr Love: On Some Neglected Corners of the Otological Field.
Cases will be shown.

ROYAL INSTITUTION, Albemarle-street, W.
MONDAY, Nov. 3rd.—5 P.M., General Meeting.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East.
TUESDAY, Nov. 4th.—5 P.M., Dr. F. John Poynton: The Prevention of Acute Rheumatism (Bradshaw Lecture).
THURSDAY.—5 P.M., Sir StClair Thomson, M.D.: Tuberculosis of the Larynx; and its Significance to the Physician (Mitchell Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
THURSDAY, Nov. 6th.—5 P.M., Mr. Raymond Johnson: Some Clinical Aspects of Carcinoma of the Breast (Bradshaw Lecture).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.
MONDAY, Nov. 3rd, to SATURDAY, Nov. 8th.—WEST LECTURE HALL, Royal Society of Medicine. Lecture arranged by the Fellowship of Medicine and open to all members of the profession. At 5.30 P.M., Monday, the 3rd inst., Mr. W. Ernest Miles: Cancer of the Rectum.—Diseases of Children (Combined Course) at the Paddington Green Children's Hospital, Victoria Hospital, and Children's Clinic. Special Intensive Course, second week.—HAMPSTEAD GENERAL HOSPITAL, Haverstock Hill, N.W. Special Intensive Course in General Medicine and Surgery, second week.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, Leicester-square. Daily demonstrations, pathological demonstrations, and lectures. First week.—LONDON LOCK HOSPITAL, 91, Dean-street, W. 1. Daily clinical work and special lectures on Dermatology, first week.—ST. PETER'S HOSPITAL FOR STONE, &c., Henrietta-street, W.C. Daily clinical work and special lectures on Urology, third week.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Nov. 3rd.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Mr. Bishop Harman: Eye Dept.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—11 A.M., Medical Registrar: Medical Wards. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept.

THURSDAY.—11 A.M., Mr. Simson: Gynæcological Wards. 12 noon, Dr. Scott Pinchin: Heart Diseases. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Deparments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

TUESDAY, Nov. 4th.—4.30 P.M., Mr. J. Howell Evans: The Pains and Penalties of the Erect Posture.

FRIDAY.—4.30 P.M., Mr. Aubrey Goodwin: Complications of the Menopause.

Daily: Medical and Surgical Clinics and Clinics in the various Special Departments, Surgical Operations, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-st., W.C.

THURSDAY, Nov. 6th.—4 P.M., Mr. O. L. Addison: The "Doctor's Dilemma" as seen in Surgical Out-patients.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Nov. 4th.—5 P.M., Dr. Knowsley Sibley: Principles of Treatment (Local).

THURSDAY.—5 P.M., Dr. A. M. H. Gray: Eruptions Due to External Irritants.

MANCHESTER MEDICAL SOCIETY (at the University of Manchester).

WEDNESDAY, Nov. 5th.—4.30 P.M., Discussion on Jaundice to be opened by Dr. F. C. Moore and Prof. A. H. Burgess.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, Nov. 4th.—4.15 P.M., Dr. J. Shaw Dunn: Carcinoma of the Kidney.

FRIDAY.—4.15 P.M., Prof. J. S. B. Stopford: The Motor Pathway.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)

WEDNESDAY, Nov. 3rd.—(At the Northern Hospital.) Dr. Stopford-Taylor: Common Skin Disorders.

THURSDAY.—(At the Stanley Hospital.) Dr. Wadsworth: Demonstration of Clinical Cases.

FRIDAY.—(At the Royal Infirmary.) Dr. F. Wilson: Modern Treatment of Urethritis.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES. (At 3.30 P.M.)

TUESDAY, Nov. 4th.—(At the Royal Hospital.) Mr. G. Simpson: Tubercular Kidney.

FRIDAY.—(At the Royal Infirmary.) Dr. Barnes: The Treatment of Diabetes.

ROYAL INSTITUTE OF PUBLIC HEALTH, Russell-square, W.C.

(Course of Lectures on the Health of the Commonwealth.)

WEDNESDAY, Nov. 5th.—4 P.M., Mr. J. R. Kerr: Invalidity from Chronic Joint Disease.

THE PEOPLE'S LEAGUE OF HEALTH. Course of Lectures on the Mind and What We Ought to Know About It.

(At the Medical Society of London, 11, Chandos-street, W.)

MONDAY, Nov. 3rd.—6 P.M., Dr. R. G. Rows: Association of Ideas, Recognition, and Memory.

Appointments.

BECKETT, A. J., M.B., Ch.B. Dub., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Kidwelly District of the County of Carmarthen.

DUGON, T. H., M.R.C.S., L.R.C.P. Lond., to be an Assistant Director of Medical Service in Nigeria.

SOLLY, E., M.B. Lond., F.R.C.S. Eng., and MILBURN, C. H., M.B., M.S. Durh., to be additional Medical Referees under the Workmen's Compensation Act for the Districts of the Dewsbury and Leeds County Courts.

Manchester Royal Infirmary:—Central Branch: Miss FRANCES A. HOGBEN, M.R.C.S., L.R.C.P., Resident Medical Officer; Miss M. L. P. GOETZE, M.B., B.S., M.R.C.S., L.R.C.P., Assistant Resident Medical Officer.

Royal Eye Hospital, Southwark: HOPE, C. W. M., M.D. Durh., F.R.C.S. Eng., Honorary Rhinologist; LIVINGSTON, A., M.B., Ch.B., M.D.S. Liverp., Honorary Dental Surgeon.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Mental Hospital.—Third Asst. P. £250.

Bolton County Borough.—Asst. M.O.H. and Sch. M.O. £600.

British Honduras.—Asst. M.O. $2430.

Cape Town University.—Wernher Beit Chair of Pathology.

Chailey, Sussex, Heritage Craft Schools.—H.S. for Orthopædi Surg. Dept. £266.

Cobham, Surrey, Schiff Home of Recovery.—Res. Sec. and Surg Supt. £600.

Durham County Council Education Committee.—Asst. Schoo M.O. £666.

Edinburgh Royal Mental Hospital.—Res. Asst. P. £350.

Fulham Infirmary, St. Dunstan's-road, Hammersmith, W.—Thir A.M.O. £250.

Hampshire County Council.—Dental S. £500.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £100.

Kensington, Fulham and Chelsea General Hospital, Richmond-road, Earl's Court, S.W.—Sen. and Jun. Res. M.O.'s for si months at rate of £100 and £75 respectively.

Leicester Royal Infirmary.—Two Surgical Dressers. 10*s.* 6*d.* weekly

Liverpool, Alder Hey Children's Hospital.—Res. Asst. M.O. £20

London Hospital, E.—First Asst. to one of the four Med. Firms £400.

Metropolitan Asylums Board Infectious Hospitals Service.—Jun Asst. M.O.'S. £500.

Metropolitan Asylums Board Mental Hospitals Service.—Tw Jun. Asst. M.O.'s. Each £500.

Plymouth County Borough.—M.O.H., &c. £1200.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.— Two Asst. Res. M.O.'s for four months at rate of £8 Also Sen. R.M.O. £100.

Queen's Hospital for Children, Hackney-road, E.—Phys. in charg of Skin Dept.

Rochester, St. Bartholomew's Hospital.—Third Res. M.O. £20

Royal National Orthopædic Hospital, 234, Great Portland-stre W.—Two Surg. Regs. £105.

Royal Naval Medical Service.—Surg. Lieuts. 25*s.* per day.

Royal Northern Hospital, Holloway, N.—H.S., Joint H.P. and Each £75. Also Cas. O. £125.

St. Mary's Hospital for Women and Children, Plaistow, E.— Res. M.O. and Asst. Res. M.O. for six months at rate o £175 and £130 respectively.

St. Peter's Hospital for Stone, &c., Henrietta-street, Coven Garden, W.C.—Third Anæsthetist. £25.

Wallasey, Victoria Central Hospital.—Sen. H.S. Also Jun. H.S £150 and £100 respectively.

West London Hospital, Hammersmith-road, W.—Surg. for Dis. o Women. Dermatologist. Also Hon. Medical Radiologis

The Chief Inspector of Factories, Home Office, London, S.W. announces the following vacant appointments: Folkeston Kent; Shilton, Warwick; Ilkeston, Derby.

Births, Marriages, and Deaths.

MARRIAGES.

CORKEY—EWART.—On Oct. 23rd, at Christ Church, Lisbur I. W. Corkey, M.C., F.R.C.S., of Epsom, Surrey, to Ethe only daughter on F. W. Ewart, of Derryvolgie, Lisburn.

DICK—ROW.—On Oct. 22nd, at the Garrison Church, Woodcot Park Camp, Epsom, James Hamilton Dick, M.C., M.B Ch.B., of Bexhill, to Dorothy Charlotte Martin, elde daughter of Lieut.-Colonel and Mrs. Row, Woodcote Par Camp, Epsom.

DODWELL—SÖRENSEN.—On Oct. 25th, at St. Nicholas, Godston Howard Branson Dodwell, M.B., Ch.B., M.R.C.S., L.R.C.P. to Dorothea Maclagan Sörensen, younger daughter o Marius A. Sörensen.

HALES—LEE-ELLIOTT.—On Oct. 22nd, at the Parish Churc Blakeney, Dr. Henry Ward Hales, of Lees Lodge, Sherin ham, to Charlotte Winifred (Pearl) Lee-Elliott, elder daught of the Rev. and Mrs. D. L. Lee-Elliott, of Blakeney Rector

DEATHS.

ALCINDOR.—On Oct. 25th, at St. Mary's Hospital, John Alcindo M.B., B.Ch. Edin., aged 51.

HOBBS.—On Oct. 20th, at the War Memorial Hospital, Hig Wycombe, after an operation, Frederick William Hobb M.R.C.S. Eng., L.R.C.P. Lond., aged 42.

STORRS.—On Oct. 21st, at Southwood-avenue, Southbourn W. H. Townsend Storrs, M.R.C.S., L.R.C.P.

WATTS-SILVESTER.—On Oct. 13th, suddenly, at Sturminst Newton, Dorset, Thomas Henry Evered Watts-Silveste M.A. Camb., B.Ch., M.B., M.R.C.S., L.R.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices o Births, Marriages, and Deaths.

ASSURANCE MEDICAL SOCIETY.—The first meetin of the session will be held at the house of the Medical Societ of London on Wednesday, Nov. 5th, when the new Presiden Dr. G. G. Howitt, will give an address on Life Assuranc its Evolution and Progress.

THE LATE DR. O. H. A. MAGGS, J.P.—Olive Henry Arthur Maggs, of Haworth, hon. anæsthetist, Victori Hospital, Keighley, who died in his seventy-third yea on Oct. 19th in a private ward at the Keighley Victori Hospital, had recently retired after practising medicin for nearly a quarter of a century at Haworth and was wel known throughout the Keighley district. A student a Charing Cross Hospital he qualified with the L.S.A. in 189 and for a time was hon. medical officer at Pimlico-road Fre Dispensary, London. At Haworth he took an active par in all branches of public life and was for 18 years a membe of the urban council. During the war he was honorar radiographer, physician, and anæsthetist at the Keighle War Hospital. He leaves a widow and one son.

Notes, Comments, and Abstracts.

ECONOMY IN DRUGS AND DRESSINGS.*

BY COLONEL L. W. HARRISON, D.S.O.,
M.B., M.R.C.P. EDIN.,
SPECIAL MEDICAL OFFICER (V.D.), MINISTRY OF HEALTH.

MY interest in the economy of expenditure of hospital materials was first stimulated by the general need for saving which arose during the war, when, in common with the commanding officers of other military hospitals, I set to work to cut down all unnecessary expenditure of hospital materials. I quickly realised that to instil economy in the use of other peoples' goods into the habits of my subordinates was a much more difficult task than I had anticipated, and it was only by constant watchfulness that waste of the kind which any reasonable person would characterise as idiotic was eliminated. Other commanding officers must have experienced the same difficulties judging by the comparison of costs in different military hospitals. Such an experience was a good preparation for the directorship of the V.D. Department at St. Thomas's Hospital, for which it was clear that the L.C.C. grant, though large, would leave no margin for waste.

Experience at St. Thomas's Hospital V.D. Centre.

Soon after taking over this department I noticed that for every patient suffering from a certain disease a certain mixture was prescribed automatically. The main reason for the prescription was a fear that the patients would think they were not being properly looked after if they received nothing to swallow. I had no objection to a *placebo*, but I suspected that this particular mixture would prove expensive when repeated many thousands of times. A consultation with Mr. Jennings, the chief pharmaceutist of the hospital, confirmed my suspicions, the price of the mixture proving to be over 8*d.* for the usual supply given to a patient. With very little trouble we worked out a prescription with the same therapeutic properties at a quarter the price, and I then had a little talk with my assistants on the subject. I said, first, that the hospital received such and such a grant for my department, so that the cost of any waste would be borne by the hospital, not by some public authority with a bottomless purse. That, of course, a patient must have what he or she really needed, but that, as they knew, many patients required no medicine, while for most others the cheaper prescription which the pharmaceutist and I had evolved, would work just as well as the more expensive which was then being prescribed as routine. My colleagues accepted my suggestions in the spirit I had hoped for, and this was the beginning of numerous little economies which have made this centre the cheapest in the matter of drugs (other than arsenobenzol) and dressings of all such centres in the country. For the patient who won't be happy till he gets a bottle of medicine though he needs nothing, Mr. Jennings suggested two mixtures which cost from one-eighth to a fourteenth the price of our first essay in economy.

Economy in Gloves and Swabs.

The expenditure of rubber gloves in a venereal diseases department is naturally heavy, as the workers in it must wear gloves for their own protection against accidental infection. I suggested that some reduction might be effected by repairing small tears. At first it was thought that repaired gloves would not prove to be safe, but, without further urging on my part, Sister Hutton, who is in charge of the nursing in the section for the treatment of females, took up the suggestion with such good effect that in 1921, when the whole department was working on a daily 8 A.M. to 10 P.M. service, and the attendances were 113,341 the expenditure of gloves was 452 pairs, as contrasted with 1920 when the expenditure of gloves was 611 pairs, though for most of the year only the section for males was open all day and the attendances were over 37,000 less. In the following year, 1922, only 442 pairs were used, though the attendances were 149,682.

Large numbers of wool and gauze swabs are used in the department, particularly for application to the bend of the elbow after venepuncture in the administration of arsenobenzol preparations. The size of each swab appeared to be rather larger than necessary and the amount of wool in each was reduced in 1921 to about two-thirds. It is impossible to state the effect in the amount of wool expended in swabs, as the figures are not separable from the total expenditure on this and other accounts, including ordinary dressings and supplies of wool to the laboratory, but the expenditure of wool in 1922 was £10 less (442 lb.) than in 1921, though the attendances in 1922 were 37,000 more than in 1921.

The result of these economies in drugs and dressings, each of them small enough in itself, is that the cost of drugs and dressings for the past two years has been 1·17*d.* and 1·25*d.* respectively per attendance, or totals of £726 to £654. It may be added that, under the admirable system of accounting at St. Thomas's Hospital, it is possible to arrive at a very close figure of the cost of each section of the hospital. All material for each department is supplied only on requisitions, which are priced and the amount debited against the department. Such a system is a great incentive to economy.

Examples from other Centres.

The experience has proved useful in my work for the Ministry of Health. When the demand for national economy resulted in the recommendations of the Geddes Committee, I feared that the stoppage of all additional expenditure on the V.D. scheme would be the ruin of my hopes of reorganising many treatment centres on efficient lines. I set to work, however, to discover money for such reorganisation as I might think necessary, by pointing out where money was being wasted, and have found a very profitable field in drugs and dressings. Often I have met with surprise that what was considered to be such a trifling matter should be thought worthy of my attention, but I have pointed out to some medical officers that, if the drugs and dressings bill in my own department were on the same scale as theirs, it would amount to over £8000 instead of an actual £726 or less. To cite a few examples :—

1. A hospital at which a small centre had been established had contracted to supply the drugs and dressings for £109 a year. The size of the centre can be gauged from the fact that this small sum worked out at 4*d.* per attendance. One year the hospital applied for a further payment of £260, by which sum they had exceeded their contract, raising the cost of drugs (other than arsenobenzol) and dressings to 1*s.* 2*d.* per attendance. Inquiry into the details elicited that no less than £117 a year was being spent on bandages. I made a guess at the cause of expenditure and offered the opinion that it is not usually necessary to bandage a patient's arm after an intravenous injection. This elicited the retort that it would be dangerous to allow a patient's shirt to come into contact with such a wound. I found later that the venepuncture wound was dressed with at least six layers of cyanide gauze, followed by a large piece of wool and several turns of bandage. Yet no dressing was applied to the much deeper wound in the much less cleanly area of the buttock which was made by way of giving an intramuscular injection to the same patient.

2. In another centre it was discovered, after the failure of the hospital to find any wastage, that in a stock mixture of iodide of potassium was another ingredient with which the iodide was really incompatible, the result being a very inelegant mixture. The cost of the effective ingredient, the iodide of potassium, was 6*d.*, that of the incompatible was 1*s.* 4*d.* The prescription had been in the hospital's pharmacopœia for many years, and the medical officer who had prescribed mist. pot. iodid. to the extent of several thousands of bottles, learnt of the presence of the incompatible and costly ingredient for the first time at a conference between the hospital and the health authority, at which I assisted.

3. In another hospital with a comparatively small turnover and a high drug bill, I found that the expenditure on a proprietary medicated pessary was £105 a year, or 8*d.* per attendance, yet the medical officer was quite ignorant of the cost, and could not name any special advantage of this particular pessary over a substitute I suggested costing a tenth the amount.

Few medical and surgical officers realise the price of the drugs and dressings which they prescribe and often use so lavishly. If they did, a little appeal on the part of the hospitals which they serve would cause them to effect such economies as would be equivalent to very substantial donations to the hospitals' funds.

---

* Abridged from the Fifth Annual Report of the Director of Hospital Services, Joint Red Cross Council.

HUMANE SLAUGHTERING OF ANIMALS.

GIVING the third Benjamin Ward Richardson Memorial Lecture, under the auspices of the Model Abattoir Society, on Oct. 23rd, Dr. Chalmers Mitchell, F.R.S., secretary of the Zoological Society of London, said that he proposed to present some evidence drawn from the Zoological Gardens as to the need of humanity and hygiene in the slaughtering of animals and the preparation of their flesh as food, and to urge that the requisite conditions could be best secured in model public abattoirs. Examination of the intestines of mammals and birds showed that the more primitive types in most classes were adapted to an omnivorous diet and that the purely carnivorous and the purely vegetarian habits were more specialised. Man, although the most highly specialised in brain, was more primitive in some other organs, including the intestines, and was more adapted to an omnivorous diet than most of his monkey relations. Until human beings modified their insides and their habits, a meat-supply would, he thought, be required.

At the Zoological Gardens, Dr. Mitchell went on to say, they had to provide meat for carnivorous and omnivorous mammals and birds. The animals chiefly used for this supply were horses and goats and these were killed in a modern, hygienic abattoir. The rifle was used, and although on an average three horses were required in two days, he knew in the last 20 years of only two cases where a second shot had been required. They had tried "humane killers," but at least for horses had found no advantage in their use. He had no personal experience in observing the use of the pole-axe or in the Jewish ritual method, but had examined evidence of experts very carefully. He was quite certain that all methods of electrocution known at present required too elaborate a preparation, upsetting to the animals, and dangerous to the staff, to be recommended. He had come to the conclusion that there was little or nothing to choose between the rifle and the humane killer, the pole-axe or the knife, skilfully used under proper conditions, as the instruments of actual death. But there were many opportunities for carelessness, ignorance, or inhumanity to inflict unnecessary suffering in the preliminaries to the final act. In his opinion these opportunities were least in the case of the rifle, relatively small with the humane killer, definite and probably nearly equal in the case of the pole-axe and the knife. If they were to be reduced to the absolute minimum, this could be done only in a large public abattoir with expert supervision.

In his opinion and experience animals had no presentiment of death, and even the fresh blood and warm offal of their fellows conveyed no message of fear to their consciousness. But they were readily thrown into panic by being driven into unfamiliar places and touched in unfamiliar ways by unfamiliar hands. He urged that every abattoir should have attached to it stables or byres of a kind to which they were accustomed, and that they should be kept in these for at least some hours before being slaughtered, and be tended and finally led out by men familiar with the handling of living animals. There would then be the least chance of panic and therefore of accident in submitting them to the weapon employed.

HYDROMINERAL STATIONS IN ITALY.

The Nord-Sud medical tour to the principal Italian spas, organised by the Italian State Tourist Office (E.N.I.T.) for foreign doctors, took place between Sept. 18th and Oct. 3rd. It was attended by over 50 medical men from England, France, Belgium, Holland, Switzerland, Germany, Poland, Hungary, Denmark, Sweden, and Finland. The tour, starting in Milan and ending in Naples, was made in a special first-class train, and was conducted by Prof. Guido Ruata, M.D., general secretary of the E.N.I.T. The participants were divided into language groups; French, English, and German, and every group was provided with a doctor interpreter. At each spa a graphic lecture was given by a medical authority of the resort, and the doctors were provided with the text of the conference printed in French, English, and German. The lecturers were: Dr. de Alessandri, medical superintendent, at Acqui; Prof. Devuto, of the Milan University, at S. Pellegrino; Dr. Gazzoletti, medical superintendent, at Levico; Prof. Viola, of the Bologna University, at Roncegno; Prof. Zoia, of the Pavia University, at Salsomaggiore; Senator Prof. Queirolo, of the Pisa University, at Montecatini; Prof. Ascoli, of Rome University, and Prof. Sabatini, medical superintendent, at Chianciano; Prof. Nazari, medical superintendent, at Fiuggi; Dr. di Tommasi, medical superintendent, at Agnano. The lectures were followed by inspection of the waters, of the establishments and other interesting points at each resort, under the guidance of the resident doctors, helped by the interpreting doctors. Everywhere the visitors were cordially welcomed. In Milan they were received officially at the palace of the Italian Touring Club by the president of the club, and at the Capitol in Rome and at the Municipal Palace in Naples by the mayors of these cities. The Italian State Tourist Office is organising a second tour for foreign doctors next year, which will comprise some of the most important Italian climatic stations in addition to the spas.

BATH MUSTARD.

We have received from Messrs. Keen, Robinson and Co., Ltd., of Carrow Works, Norwich, a specimen of the new form of packing for this pleasant and useful addition to the bath. The mustard is now put up in a tin canister with a hinged lid, and the decorative design on the enamelled exterior makes the mustard container an elegant ornament for the bathroom. The price is 2*s.* 6*d.* per canister.

MIRROR-WRITING IN AN ADULT.

To the Editor of The Lancet.

Sir,—Referring to Dr. V. Pendred's letter on this subject in your issue of Sept. 27th (p. 684) I know a young lady of over 30 years who can mirror-write with either hand. She is naturally left-handed and writes more easily with that hand for her mirror-writing and more easily with her right for normal writing. She can write normally with her left hand also. She can also write simultaneously with the two hands. I enclose a copy of her handicraft. The four types of writing are remarkably similar.

I am, Sir, yours faithfully,

Oct. 18th, 1924. M.B.

MIRROR-WRITING AND LEFT-HANDEDNESS.

To the Editor of The Lancet.

Sir,—I should like to record another instance of the association between mirror-writing and left-handedness. It is the case of a little boy almost 8 years old. He has always been left-handed. As soon as he began to learn to write it was noticed that he was forming certain letters in the reverse direction—that is, from right to left (ᗺ. Ǝ), which is mirror-writing. It is not my object at the present time to offer any speculations upon the meaning of the association between mirror-writing and left-handedness. I merely wish to record one more case of the concurrence of these two peculiarities, the source of which must ultimately consist in some kind of atypical cerebration.

I am, Sir, yours faithfully,

Dane Hill, Sussex, Oct. 20th, 1924. D. Fraser Harris.

MANCHESTER LOCAL VOLUNTARY HOSPITALS COMMITTEE.

The report just issued emphasises the vast extent of the work done by these institutions and the need there is for greater public support. In the 17 local hospitals last year there were 194,093 new out-patients and 28,140 new in-patients. The total ordinary income was £236,220 and the expenditure £274,504, leaving a net deficit for the year of £38,278. The committee is of opinion that the voluntary system should be maintained and is worth saving, but it is felt that only the public can adequately answer the question by a generous response to the appeal for funds. The committee has come to the conclusion that a very large measure of support has failed to accrue by reason of the lack of centralised effort—there is not sufficient cohesion in the efforts at present being made. Centralised efforts have been successful in other towns to keep the local hospitals out of want, and success has crowned such efforts. The Voluntary Hospital Committee is therefore of the very strong opinion that such an object should be attempted in Manchester and Salford with a view to stimulating the existing agencies, and also to ensure that all avenues of support are fully explored.

A WHIFF OF OLD TIMES.

The contents of a commonplace book compiled for medical men may be useful for bedside reading. Dr. John Wishart has collected a hundred extracts [1] from literature prior to 1850 of mixed quality. Occasionally we come upon an extract which has a good flavour, such, for instance, as No. 51 from Coghan's "Haven of Health," 1636.

> "Now what Cheese is well made or otherwise may partly be perceived by this old Latine verse:—
>
> Non nix, non Argos, Mathusalem, Magdalanaene,
> Esau, non Lazarus, caseus ille bonus.
>
> That is to say, Cheese should not be white as snow is, nor full of eyes as Argos was, nor olde as Mathusalem was, nor full of whey or weeping as Marie Magdalen was, nor rough as Esau was, nor full of spots as Lazarus was. Banburie Cheese shall go for my money, for therein (if it be of the best sort) you shall neither taste the renet nor the salt, which be two special properties of good Cheese."

Another interesting extract is No. 10, being an account of a case of precocious puberty in a boy who died at the age of 7 "with all the signs of extreme old age and as if the months he had lived had been years." This is taken from the *Gentleman's Magazine* for December, 1734. The child must have been the original of Gilbert's "enfeebled old dotard of five."

An Address

ON THE

GENERAL PRACTITIONER AS A RESEARCH WORKER.

Being the Presidential Address delivered to the Fife Medical Association on Sept. 26th, 1924,

BY J. H. P. PATON, M.B., CH.B. EDIN.,
SECRETARY, ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

[Dr. Paton, referring to the fact that at the present time research into the ætiology of diseases is almost wholly bacteriological, deprecated any impression that studies which could not be corroborated by laboratory investigations were the less trustworthy. The annual wastage from sickness and disability, which in England and Wales alone had been estimated at £150,000,000 per annum, was a problem left practically untouched by systematic research, and it was essentially one on which light could be thrown by the concerted experience of practitioners. Unfortunately it was rare to see articles by general practitioners recording and analysing their clinical experiences or dealing with the commonplaces of everyday practice. Such individual efforts as had been made were sporadic and not coördinated, and had not until recently been assisted financially. The Medical Research Council had, however, instituted grants for a few general practitioners engaged in special researches, and the B.M.A. had offered a prize for similar work. The difficulties in the way of the general practitioner were still enormous. The earning of his livelihood occupied almost every moment of his time, and any leisure that he had from his practice found him eager to get some hard-earned rest or recreation. Should he require laboratory assistance for experimental verification of his views, he had no convenient means at hand and no close association with the laboratory worker. Above all things he lacked the stimulus of working with colleagues for a common cause. The view he wished to put forward was simply that, if means were supplied by which systematic research into the problems of his practice could be continuously carried on by every general practitioner throughout the country, there was every reason to anticipate that benefits as great would accrue to general medicine as had been achieved by concerted research in the case of tropical diseases. Dr. Paton continued :—]

CLINICAL RESEARCH ESSENTIAL.

The research to be undertaken in this field is not mainly laboratory research. It has to do with observations at the bedside, not merely the recording of symptoms, but the study of them, so as to determine the laws that govern their production and the physiological processes that underlie them. Laboratory aid will be constantly required for experimental verification of the results, but the main function of the worker will be exercised at the bedside, and his results will be obtained by true clinical research. It is a common belief, expressed audibly and with great candour in some quarters, that the general practitioner is incapable of carrying out research. There is, at any rate, no systematic attempt made to teach the medical student the principles upon which it should be undertaken, and any scheme for utilising the mass of general practitioners for this object is regarded as impossible and impracticable. The foundation of the St. Andrews Institute for Clinical Research by Sir James Mackenzie was an expression of his conviction that such a view is untrue—that not only is the general practitioner capable of carrying on research, but that he is eager to do so if opportunity be given to him. Sir George Newman, in his est report, acknowledges that research is essential in view of the mass of sickness and disability. He estimates the loss of working time from this cause at 20½ million weeks every year. But as yet he does not appear to realise that this research can only be undertaken by the men in contact with the facts—by the general practitioners of the country—that time and means must be given to them for this purpose and their work coördinated.

THE WORK IN PROGRESS AT ST. ANDREWS.

We have in this Institute, in a small way, the organisation necessary for these objects. The generosity of a few private individuals who understand Sir James Mackenzie's point of view enabled us to establish it and provide for its administration. The Carnegie Trustees gave us a grant to pay the salaries of a chemist and a bacteriologist for a period of five years, now, alas, nearing an end, and the Medical Research Council aided us with a generous grant, the objects of which were to associate with us the professors of anatomy and physiology—to provide the salary of a whole-time physician engaged in the study of infants and children, and to meet some of the necessary expenses in regard to record-keeping and radiography; thus we are equipped not only with clinicians but with the experts necessary for carrying out special investigations.

We have now been at work for five years. Our clinical staff consists of some half dozen persons on part-time duty. I hope to be able to convince you that the experiment has justified itself—at any rate, that it has demonstrated that the idea of the general practitioner devoting some part of his time to research is not only feasible but is capable of producing results of practical value. We had no special qualifications for the task, except that we are general practitioners in daily touch with the problems requiring investigation. Indeed, there were no special qualifications to possess, because the field is a new one. We had to invent our own methods and train ourselves in their use, nor are either the methods or the training as yet by any means complete. As the laboratory worker requires strenuous training to master the technique of existing methods, and as he has constantly to be devising new methods to overcome fresh difficulties, so must the worker in clinical research train himself in known methods and continually devise better ones to supersede them. We have advanced some little way in both of these directions, in formulating a plan of campaign and in training ourselves in the best ways of carrying it out.

Case-taking: The Meaning of Symptoms.

Our first endeavours were devoted to devising methods of case-taking and of recording symptoms—methods suitable to that class of case in which we are interested—the minor ailments and disabilities in which structural change, or at any rate detectable structural change, is conspicuous by its absence. Our methods for recording symptoms were planned with the idea of bringing out those facts which would throw light upon the mechanism involved. These methods are constantly being revised and modified as our point of view changes and our experience widens. In particular we have endeavoured to record in special detail those circumstances of environment which may be supposed to disturb health and favour the onset of disease—habits, mode of life, both at home and at work, and the family history. But the essential feature of the records on which we lay stress is that they should be continuous, should include in chronological order every change as it appears from the first disturbance of health to the termination of a disease, for disease is a consecutive series of disturbances of health rather than a morbid state which can be comprehended from a description of the patient's symptoms at any one moment. Upon a knowledge of this procession of events (of the natural history of each disease) and of the processes which underlie each, depends scientific prognosis, and prognosis, as

Sir James Mackenzie has aptly expressed it, is the breath of life to medicine. We must be able to say in regard to obscure states of health: "The symptoms indicate the presence or absence of progressive disease," or "The appearance of a new symptom indicates a more serious state of affairs while the disappearance of another indicates betterment." While upon our decision as to whether a symptom is harmful or beneficial, is likely to disappear of itself or to progress to something worse, must depend the whole of intelligent treatment.

It is one of the fundamental axioms laid down by Sir James Mackenzie that the symptoms of use for diagnosis are not, as a rule, those of value for prognosis—an axiom based on the fact that structural changes are only of importance in so far as they disturb those functional activities which affect vital processes. Evidence of interference with function is to be sought for in symptoms rather than physical signs, and, as a rule, in symptoms referable to some other system or organ than the one structurally affected. That this is true in the case of the heart is obvious enough. Enlargement, dilatation, a valvular lesion, &c., give evidence of their danger to life in symptoms due to the deficiency of circulation in other organs—breathlessness, syncope, œdema, &c. What is true of the heart is true of other systems. Disease of the kidneys becomes dangerous to life when their functional efficiency as eliminating organs is impaired. And we know that the danger signals are to be looked for in changes in the heart and blood-vessels, in cerebral disturbances, such as headache or convulsions, and in breathlessness, œdema, &c. To estimate the prognosis, the probable course, the duration, the handicapping quality of a man's illness is not only a more difficult, but in reality a more important duty than to make an accurate diagnosis. But before the prognostic significance of a symptom can be scientifically understood it is essential that the processes underlying it should be known. When this information has been acquired about all symptoms, our understanding of a disease will have become rational and our prognosis will be based upon scientific data. Here lie the basis and fundamental task for clinical research—the acquisition of the knowledge of the mechanism by which symptoms are produced. This must be the aim of all our work, to put symptomatology upon a scientific basis.

The Reflex Hypothesis.

We believe that the first great step in this direction has been taken by our formulation of the reflex hypothesis—viz., that the majority of the symptoms of disease are due to disturbance of normal reflexes, and must be looked upon as disturbed physiological reactions of the body rather than as the properties of disease. No cell exhibits its specific activity except in response to stimuli which arise in the case of unicellular and low organisms in the environment and mobilise the cell by direct action. In the case of the higher organisms, where action at a distance is essential, these direct stimuli are converted by the activity of the receptor cell involved into impulses which are transmitted to the appropriate effector cell by a nervous connexion which we know as a reflex arc. The normal response of the body to the flood of stimuli from its environment is what we call health, and it is represented in consciousness by a sensation of well-being. If the impulses from any receptors be excessive, disordered, or diminished, then the response of the effectors becomes abnormal, the sensation of well-being is lost, and a symptom results. The task of the investigator of symptoms is thus made clear, to trace back the abnormal impulses from the effector to the disturbed receptor in which they originate. This broad conception, once it is realised, does more than this, for it furnishes a rational basis for the classification of symptoms, a basis determined by the nature of the processes involved into two great fundamental divisions—structural and reflex. The structural symptoms are what we know as physical signs. But it is with the reflex symptoms, the functional disturbances with which we as general practitioners have mainly to deal, that this hypothesis is concerned.

I need not tell you that, as general practitioners, our ignorance of reflex arcs and their connexions and habits was abysmal. But here the value of the coöperation of specialists became immediately apparent. Prof. P. T. Herring grasped the significance of the hypothesis, and in a series of addresses to us, afterwards published,[1] discussed and elucidated what was known in regard to reflex processes. In the course of these studies it became evident that there exists little accurate information about the nature and action of receptors. It is obvious, for example, that pain is commonly the result of the application of certain stimuli to the skin, but that on the application of these very stimuli to certain other tissues in the body no pain results, although these tissues can give rise to the most acute pain in certain circumstances. Pain in such cases, then, is not dependent upon the specific nature of the stimulus applied, but upon the nature and activity of the receptors involved. A committee, under the chairmanship of Prof. David Waterston, undertook a study of this question, and the results are being published from time to time.[2] In the course of their investigations there has emerged the fact that sensitive points in the skin vary in their activity. They are sensitive at one time and insensitive at another. Moreover, as one spot becomes insensitive another in the neighbourhood takes up the function. It has been shown by Krogh and others that there are similar variations in the activity of the capillaries of the skin of muscle and of the glomeruli of the kidney. This alternation of rest and activity we named fluctuation, and it became evident that some such property as this must be postulated for all cells—if the continuous action of organs is to be explained—and to account for such phenomena as the graded response of organs and the occurrence of reserve force.

Prof. Herring explained this view in a paper published in *Brain*,[3] which received but scant appreciation at the time. But it is interesting to note that in the Biological Section of the British Association this very property of living cells was placed in the forefront of the programme. I have mentioned these matters to show you the direction in which the theoretical side of the research is heading. But meanwhile much clinical information of practical importance is being accumulated and analysed.

Clinical Investigations.

The feeding of infants and children and the effects upon them of insanitary and disturbed surroundings are being specially studied. Dr. Andrew Rowand has many records in his possession demonstrating the disturbance (or conditioning) of normal reflex processes by environment. Certain ill-nourished infants, brought up in noisy and quarrelsome homes, fail to respond to the most careful regulation of their diet, but improvement at once follows if they are placed in proper and restful surroundings.

Many children suffer from anorexia during school term, though they eat well during the holidays. It needs little stretch of imagination to suppose that the continuous inhibition of gastro-intestinal reflexes which must be present in such cases may lead to a permanent disability and even to structural disease.

The relationships of nasal catarrh to adenoids, of sore throats to the enlargement of tonsils, of "growing pains" to rheumatism, are being illustrated by consecutive series of cases. Special attention is being given to the recurrent ailments of childhood—nasal and bronchial catarrhs, sore throats, cyclic vomiting, &c., and in all cases we attempt to make the record continuous, so that eventually we will have a clear idea of the effects upon the adult of these childish ailments.

Our records of adult patients consist either of cases of obscure ill-health, of cases exhibiting some special symptom in a marked form, or of cases of definite diagnosable disease. The obscure cases of ill-health may be temporary or may be prolonged, leading eventually to one of the diagnosable diseases. We attempt to record in each the points that appear likely to be of value in advancing the knowledge of diagnosis, prognosis, or the mechanism of symptoms, and these points are catalogued for each case so that they may be available for future reference. And here again we insist on continuity of the records so that the ultimate outcome may be apparent.

Attempts are made to unravel the mechanism of a particular symptom by the study of a series of cases exhibiting it. In connexion with the study of pain, for example, Dr. James Orr has collected a number of cases where the symptom appears to be due to deficiency in the supply of blood to muscle, not only cardiac muscle but skeletal muscle as well. He is also specially devoting time to cases bearing on the mechanism involved in the maintenance of blood pressure. All this is bound up, as you can see, with the subject of arteriosclerosis, its causes, onset, advance, and termination, and its effects on the function of the various organs which it attacks.

Exhaustion is being studied by Dr. L. H. Bryson. As a result of his work upon this subject the vital importance of capillary activity, already touched upon in the work on fluctuation, is becoming manifest. Capillaries can no longer be regarded as passive structures meekly accommodating such blood as is delivered to them by the activities of the general circulation. We have seen that they vary in their activity, both in the skin and in glomeruli. And it is becoming clear that so far from the circulation controlling them, it is to a large extent their servant, and it is to meet their demands that cardiac and vasomotor mechanism is mobilised. One of the factors which most potently disturbs the reflex mechanism, whatever it is, which regulates capillary activity, is the occurrence of toxæmia, and in a large series of cases of exhaustion the clinical evidence points both to disturbance of capillary circulation and to the presence of a toxin in the blood.

In addition to such works on the mechanism of symptoms we are endeavouring, as far as we can, to collect records which will demonstrate the truth or falsehood of many traditional beliefs which are widely held—for example, the belief that pleurisy is commonly tuberculous, that hæmoptysis is almost invariably so, that rheumatism is frequently the result of tonsillar disease and is relieved by the removal of these organs, that pain is the characteristic symptom of gastric and duodenal ulcer, and that these conditions can be accurately differentiated by the time of onset of the pain as is taught by Moynihan, that measles predisposes to tuberculous infection. Each of these is at present a pious belief adhered to with great tenacity in some quarters and scoffed at in others, each observer relying on the evidence of records which, though their authors are quite unaware of the fact, are selected records. The tuberculosis expert sees nothing but cases of phthisis. He sees no pleurisy except among those cases, a large proportion of whom give a history of previous pleurisy. What more natural than to conclude that pleurisy is invariably evidence of tuberculous infection? That conclusion may be right or it may be wrong, but the only arbiter must be the general practitioner who sees every case of pleurisy and who can follow each to its ultimate outcome.

CONCLUSION.

I have given you these details of our work here, not because we are particularly proud of them, not because they represent anything epoch-making, but because they show that there is this work to be done and that the general practitioner is capable of doing it, if time and means are provided. I have tried to show you that there is this great undiscovered country to be explored. But it is evident that it is not to be conquered by the efforts of a few pioneers, however eager they may be. A fully organised force must attack it, from a definite base, and after roads have been opened up permitting their entry. I have tried to show you that that force must consist of the general practitioners of this country, with the necessary ancillary services at their disposal to clear the path for them, physiologists, anatomists, bacteriologists, chemists, radiographers, &c., whose expert knowledge will be devoted to the quest in hand. Through the facilities which we possess at this Institute, under the guidance of a great and far-seeing leader, we have been enabled to establish such a base and to drive a little path from it into the wilderness. Sir James Mackenzie can, alas, no longer bear the strain, but his office has been filled by one of his most ardent admirers and disciples, Dr. Maitland Ramsay, under whose leadership we will continue the research.

Gentlemen, to each of you must have come, some time or another, the opportunity, and with it the desire, to investigate some problems in your daily practice, but facilities were wanting and the stimulus of comradeship and a common purpose. We have the facilities, in rudimentary but workable form, at this Institute, and my object to-day is to assure you that these are at your disposal, and to endeavour to enlist your help, your sympathy, your advice, and your criticism in this campaign. Some of you already work with us, to your own benefit, I hope, and certainly to our great encouragement and assistance, and I would appeal to this association for more recruits. The Institute, with its records, its library, its laboratories, its meetings, with the knowledge and advice of its specialist staff, and with the coöperation of its ordinary staff, is at your service for the investigation of the problems of your daily work. If you cannot afford the time to come to St. Andrews a letter to the secretary will place any information we may have at your disposal. And if you have records of interest compiled in your practice and can let us have them to add to ours, we will be greatly in your debt. I look forward to a time when all this will be accepted doctrine, when institutes such as ours will be set up in every district in the country, and when part of the duty of each general practitioner will be to take his share in clinical research. Meanwhile let us do what we can, let us lay the foundations for that movement, a movement which will, I believe, achieve for general medicine no meaner triumphs than those described by Sir David Bruce at Toronto as having been effected for the tropical diseases—a movement which will lead eventually, through the discovery of the laws governing its phenomena, to the elevation of medicine from an empiric art to its true place as an applied science.

JOHANNESBURG GENERAL HOSPITAL, SOUTH AFRICA.

The honorary surgical registrar at the hospital reports that, during the year ended March last, 305 cases of cancer were treated at that hospital—an increase of 18 over the number during the previous year. This year the number of deaths from cancer was 74, against 81 during the previous year. But despite this decrease in mortality the number affected by the disease is still on the increase. During the same year, ended March last, as many as 557 persons were admitted to the hospital suffering from appendicitis. Only 30 of the number were natives, but of the 30, six died, whereas only 15 out of the 527 Europeans died. The registrar admits, of course, that the death-rate among natives suffering from appendicitis is very high—20 per cent., as compared with 2·8 per cent. for Europeans; but this is mainly due to the fact that natives have not yet learned to seek medical advice early.

ON

TUBERCULOSIS OF THE LARYNX:

ITS SIGNIFICANCE TO THE PHYSICIAN.

Delivered before the Royal College of Physicians, London, on Nov. 6th, 1924,

BY SIR StCLAIR THOMSON, M.D. LOND.,
F.R.C.S. ENG.,
CONSULTING SURGEON, DISEASES OF THE THROAT, KING'S COLLEGE HOSPITAL; LARYNGOLOGIST, KING EDWARD VII. SANATORIUM, MIDHURST.

TUBERCULOSIS is the most important disease with which humanity has to cope. There is no other specific disease so common in the larynx. As the 106,990 cases of laryngeal tuberculosis in this country to-day must look principally to the physician for guidance and help, it is well worth while considering what assistance in his task can be offered by a laryngologist who, during a period of 10 years, has carefully watched the progress of 477 instances of laryngeal disease in 2541 patients with pulmonary tuberculosis.[1]

Proportion of Laryngeal Cases in Pulmonary Tuberculosis.

In the early years of this period 1 case out of every 4 had trouble in the larynx, while the average of the whole decade showed a proportion of 18·77 per cent. These patients were seen in a sanatorium and were, relatively, early cases, for the records of the post-mortem room show that the larynx is diseased in 48 to 83 per cent. of all fatal cases.

Suggestive Symptoms.—The two most suggestive symptoms are, first, slight but persistent huskiness, and secondly, discomfort referred to the throat or even pain in swallowing.

The latter is a symptom which is more frequent with advanced cases; therefore, for the all-important attainment of an early diagnosis, any hoarseness or any slight change in voice which does not clear up in two or three weeks should rouse suspicion and entail an expert examination of the larynx. But we must not forget that tubercle occasionally invades the larynx without causing the slightest alteration of voice or any other local symptom. Of the 477 cases of laryngeal tuberculosis I found no less than 57 (34 men and 23 women) who had no complaint of their throat and whose voices, both to their own ear and to mine, sounded quite clear and normal.

Proportion of Laryngeal Cases in Relation to Sex.—It used to be thought that the female sex was less subject than the male to contract pulmonary tuberculosis. But it has been shown that any difference between the sexes in this respect is not, as regards tubercle, due to any sexual predisposition but simply to the fact that, until recent times, women have led a more sheltered life and have been less exposed both to fatigue and to infection than men who work in office or factory. When both sexes are exposed to the same conditions, woman is just as subject to tuberculosis (in lungs or in larynx) as man; perhaps more so. The conclusion is that, amongst breadwinners, we must be prepared to find tubercle just as frequently in the larynx of the female as of the male. Another is that man's greater indulgence in alcohol and tobacco does not seem to render his larynx more vulnerable to tuberculosis.

Proportion of Laryngeal Cases in Relation to Stage of Pulmonary Disease.—It has long been established that the frequency with which the larynx is invaded increases with the progress of the pulmonary disease. This may occur even in 4·8 per cent. of cases in an early stage of the disease. These are cases with limited lesions and, at this period, might well be called "favourable." In severe cases the proportion mounts up to 18·3 per cent., while in the advanced type of disease which forms Group III. of the Turban-Gerhardt classification the proportion of laryngeal disease is almost double—viz., 31·5 per cent. Both women and men are increasingly liable to a laryngeal lesion with the progress of the pulmonary disease. Only 1 out of every 20 poitrinaires with an early lesion is liable to throat trouble; in more serious cases—i.e., those in Group II. of the Turban-Gerhardt classification—the proportion may be 1 in 5; and in the advanced cases of Group III. 1 patient in every 3 will have the disease in the larynx. This development, as will soon be shown, diminishes so markedly the prospect of recovery that it emphasises the great importance of diagnosing pulmonary tubercle in its early stage and persuading the patient to submit to the best treatment.

Region of Larynx Attacked.—It is quite certain that the favourite site is the neighbourhood of the posterior commissure—i.e., the interarytenoid area, the anterior surface of the arytenoid body and the vocal processes. The vocal cords come next in frequency, while the epiglottis and the region of the anterior commissure are attacked more rarely and are generally late extensions of the disease.

Prognostic Value of Tuberculosis of the Larynx in Regard to Mortality.

Of much importance to the general physician is an appreciation of what tuberculosis in the larynx counts for in regard to the mortality of pulmonary cases.

Of the 2541 patients with pulmonary tuberculosis who were discharged from the King Edward Sanatorium, Midhurst, between 1911 and 1921, the proportion of those alive between one and ten years later was, amongst those with a sound larynx, double that of those with tuberculous laryngitis. Of patients found to have tubercle in the larynx during these ten years, 2 out of every 3 were dead. Of those with a sound larynx it is the reverse—2 out of 3 were still alive. Of all the 477 cases of laryngeal tuberculosis which passed through my service at Midhurst between 1911 and 1921 no less than 70·5 per cent. are now dead. This darkening of the prognosis occurs in all stages of the disease.

Put in another way, a Group I. patient—i.e., a "slight" case—with a laryngeal lesion has a worse prospect than a Group II. case with a sound larynx. And a Group II. case—i.e., a "severe" case—with throat trouble has a gloomier expectation than if he had had a healthy larynx but lungs so invaded as to be classed in Group III.—i.e., an "advanced" case. Therefore laryngeal tuberculosis cannot be listed in any group which might be termed "slight" or "favourable." Its discovery at once labels a case as "severe," and authorises a physician to warn his client that treatment will necessarily, even in the most hopeful cases, be long and arduous. In only too many instances—in 70·5 per cent. of my fairly favourable selection—it will be his duty to advise the friends that the prospect of a recovery is so slight that it may be unjustifiable to submit the sufferer to any trying, dangerous, or expensive treatment.

Results of Treatment.

Let us now turn to the record of 119 cures. To appraise them at a fair value I may be permitted to say that such a large total of well-authenticated cases of healing in a larynx with tuberculosis has never before been published in this country. The satisfaction of quoting this record is enhanced when I recall that in 1880 Morell Mackenzie wrote: "The prognosis of laryngeal phthisis is always extremely unfavourable, and it is not certain that any cases ever recover." A complete repair of the larynx has been obtained in no less than 25 per cent. of patients with tuberculous laryngitis.

Cures: How Obtained.—I have no doubt that the principal factor in obtaining these arrests has been *sanatorium régime* and the prompt prescription of one or more of the three chief methods of local treatment—viz., whispers, silence, and the galvano-cautery. Fifty patients were cured, so far as local measures are concerned, by the simple reduction of voice use entailed by "whispers." Complete *silence* resulted in a cure in 23 instances, or in 34·3 per cent. of the cases in which it was ordered. Women give a slightly higher percentage of cures, both with whispers and silence, their greater patience and endurance—or recovery power?—being most noteworthy in the ordeal of the silence cure. The *galvano-cautery* yielded 46 cures.

---

[1] StClair Thomson: Tuberculosis of the Larynx. Ten Years' Experience in a Sanatorium. Medical Research Council. H.M. Stationery Office. 1924. 2s. 6d.

Lasting Laryngeal Cures.—Of the 119 cases in which complete healing took place in the larynx, 69 are alive at periods varying from 2 to 10 years afterwards. Fifty are dead, and they have died, as a rule, with a still cicatrised larynx. Their deaths, usually, were due to the extent or virulence of their pulmonary disease.

Proportionate Progress of Pulmonary and Laryngeal Lesions.

The above references to the durability of healing in the larynx, while the disease in the lungs progresses, are sufficient to show that tubercle does not necessarily advance pari passu in both situations. This latter view is still maintained and, as it is not correct, it may occasionally mislead the physician. Improvement very commonly does proceed along parallel lines and, in the same way, a retrogression in one is often followed by progress of the disease in the other. Spontaneous cure has taken place in the larynx in many cases and has been maintained till the patient died of his pulmonary disease years afterwards. But the reverse has never occurred—i.e., I have never seen a larynx getting worse while the pulmonary disease has improved. It has occasionally, in such instances, been reported to me that the lung trouble was in statu quo; but, if the larynx did not mend, the pulmonary disease inevitably, within a definite period, took on activity.

This is useful knowledge for the physician. A larynx may improve or get well, while the lung disease remains quiescent or gets worse; but if the disease in the larynx advances the pulmonary disease cannot possibly become arrested and soon makes progress. This again shows the value to the physician, from the point of prognosis, of periodic examination of the larynx.

Tuberculosis in the larynx is always a serious complication of pulmonary disease. Physicians would be well advised, therefore, to assure themselves of its presence or absence in any case of tuberculosis. If present, it adds considerably to the seriousness of the prognosis and to the prolongation of the case and time required for successful treatment, even in cases otherwise early and promising. When the laryngeal lesion is extensive and active, the outlook is particularly serious. If the lesion is limited and becomes inactive, it may be arrested, although the prospect of life may not be great.

From prolonged observations on nearly 500 sanatorium patients, a cure of the laryngeal lesion may be secured in 1 out of every 4 patients. These were, comparatively speaking, early cases. But a much higher proportion of cures could certainly be obtained if more cases of pulmonary tuberculosis were diagnosed while they are still Group I. patients—i.e., with only 4·8 per cent. showing laryngeal lesions—instead of Group III.—i.e., with 31·5 per cent. with the larynx involved. More cures could be effected if every case of persistent huskiness or throat discomfort were earlier submitted to a skilled examination.

Principles of Success in Treatment.

It is manifest that a patient has a more sure hope of a quicker cure inside a well-conducted sanatorium than he can expect otherwise. The chief local requirement is voice rest, which can be so easily carried out in a sanatorium, but is elsewhere so difficult. Out of 119 cases which were cured, the healing was obtained without other local treatment than voice rest (whispers or silence) in no less than 73 instances. Local surgical methods of cure have all been abandoned by me as useless and frequently harmful.

The galvano-cautery is the best local treatment we have at present. In suitable cases it has replaced all other methods. It effected a cure in 46 out of 74 cases in which it was tried (=62·1 per cent.). Of these 46 cures, 29 are alive and well: 12 of them have now maintained their cure for 10 years.

Conclusions.

The majority of cases of tuberculosis of the larynx do not recover. It is necessary for the physician to recognise this; to try and determine which cases come within this category, and to act accordingly. But these 119 cures are witnesses of the more hopeful outlook we now have for a fair proportion of patients of whom an authority has said that, 45 years ago, "all were doomed to die: the appearance of the disease in the larynx was the warrant of death."[2] The pessimistic past has now a more optimistic outlook.

DIPHTHERIA PREVENTION.

THE SCHICK TEST AND ACTIVE IMMUNISATION IN VARIOUS SCHOOLS AND INSTITUTIONS IN THE CITY OF EDINBURGH.

By W. T. BENSON, B.Sc. St. And., M.D. Edin.,
D.P.H. Camb., D.T.M. & H. Lond.,
ASSISTANT MEDICAL OFFICER OF HEALTH.

Introduction by

Wm. Robertson, M.D. Glasg., D.P.H., F.R.C.P. Edin.,
MEDICAL OFFICER OF HEALTH.

At the recent Conference of the Royal Sanitary Institute, held at Liverpool, the fear was expressed, or implied, that the introduction of the Schick test and the consequent immunisation of susceptible subjects by means of toxin-antitoxin would not meet with much success in this country. The reason offered was that our people had not been educated to the need for the procedure. If we had adopted such a *non possumus* attitude in Edinburgh we should possibly have shared the pessimism expressed during the discussion of Dr. R. A. O'Brien's excellent contribution. It is a mistake to underrate the intelligence and interest of the citizens of our respective administrative areas. They are keenly alive to the importance of prevention of disease. It was with that knowledge in my mind that a campaign of diphtheria prevention was begun in the Leith district. The response to our appeal for coöperation was most encouraging. Dr. Benson, my assistant, at once set to work and the results detailed in his valuable contribution should act as an incentive to others to go and do likewise. It is not work that can be lightly undertaken. Careful readings must be made by those who have studied a considerable number of reactions. Objections will naturally be offered to the procedure. We have experienced them.

Every effort was made by the "antis" to cast doubt on the value and safety of the various applications that were required. The most was made of accidents that had occurred in America and that had been duly explained. The members of the school authority were circularised, the press was tried, and the members of the public health committee were tempted, but no difficulties confronted us as a result of the attempted obstruction. I feel confident the results will convince hesitating parents that the procedure is not only safe but also wise. During the ensuing winter months the campaign will be continued, and when more facts are available they will be published. The figures given by Dr. W. H. Park, of New York, together with Dr. A. Zingher's interesting data, were so convincing that no doubt was left in my mind as to the need for doing more to reduce the incidence of diphtheria than the swabbing of throats, quarantining of contacts, and the costly treatment in isolation hospitals. It was only after Dr. C. B. Ker, the medical superintendent of the Edinburgh City Fever Hospital, had fully satisfied himself as to the efficacy of the Schick test and the safety of immunisation by toxin-antitoxin that the resolve was made to undertake a comprehensive scheme in the Edinburgh area.

---

DIPHTHERIA PREVENTION. BY DR. BENSON.

Diphtheria in Edinburgh.

In Edinburgh during the past five years we have isolated 5154 cases of diphtheria, including 687 carriers. Out of this number, 330 deaths occurred. An analysis of the above figures shows that whilst only 24·3 per cent. of the five thousand odd cases occurred in children under 5 years of age, this age-period accounted for no less than 60 per cent. of the total deaths. On the other hand, 75 per cent. of the cases occurred in children of school age and in adults with, fortunately, a diminished mortality-rate.

The ideal in any scheme of immunisation against diphtheria, as pointed out by many workers, would be to protect the susceptible child towards the end of the first year or in the second year of its life. This ideal, however, presents considerable difficulties in attainment. Where three-quarters of the diphtheria patients are 5 years of age or over, we may be justified in assuming that by protecting the susceptible children of school age, particularly in the infant classes, the diphtheria incidence should be diminished by at least a half to three-quarters.

The Start of the Scheme.

In May and June of 1923 a sharp outbreak of diphtheria occurred in a school in the Leith area. The ordinary methods of control, vigorously applied, were not found effective, and as a last resort, the holiday season being almost due, the school was closed. With this epidemic fresh in the minds of the parents, a good opportunity presented itself for advocating the application of more modern methods—namely, the Schick test and subsequent active immunisation of susceptible children. Early in November, under the auspices of the Parents' Association, a meeting was convened at the school. This meeting, very largely attended, was addressed by Dr. Robertson, the medical officer of health, and by Dr. Ker, the superintendent of the City Hospital. The Schick test and methods of immunisation were explained. Experience in the application of these methods, both at home and amongst school-children in New York, was quoted.

The Edinburgh Education Authority was then approached, and in December gave the Public Health Authority permission to carry out diphtheria prevention work in their schools in the Leith area, with the proviso that they accepted entire responsibility and, secondly, did not call upon the school medical staff for assistance. Early in January of this year the work was commenced.

Procedure Adopted.

A personal visit was paid to the headmaster of each school, when the methods and aims of the work were explained, and an endeavour made to enlist his active sympathy and support. For his information a memorandum on the Schick test and active immunisation, specially drawn up by Dr. Ker,[1] was presented to him.

As it was anticipated that the advice of the family doctor would influence many parents to grant or withhold consent, a copy of this memorandum was issued to each general practitioner in Edinburgh previous to the start of the campaign. Later experience showed the great advantage, both in obtaining a larger percentage of consents and in expediting the work generally, of obtaining the active interest and support of the headmaster and teaching staff. Zingher,[2] in his work in New York schools, emphasised the importance of obtaining the coöperation of the teaching staff.

The number of children attending the school up to the tenth birthday having been obtained, the requisite number of information leaflets and consent slips was supplied for distribution.

Information Leaflet.

Diphtheria is a dangerous infectious disease which mainly attacks children.

In Edinburgh we have more or less 1000 cases of diphtheria each year, and out of these some 70 to 80 children die.

There is now a safe and reliable means of preventing diphtheria.

By the use of a simple test (Schick test) it is possible to find out those children who are liable to take the disease and those who are not.

Those children who, by this test, are found to be susceptible to diphtheria can be protected against the disease.

Protection is obtained by a course of three small injections at weekly intervals.

Many thousands of children have been tested and protected in this and other countries, *and the methods employed have been proved to be effective and harmless.*

Facilities for testing and protection will be made available at every school as the need arises.

Children of under school age should be sent to the school with an older brother or sister in order that the various procedures may be carried out.

I strongly advise you, in the interests of your children, to have them protected against diphtheria. Once protected, it is believed they will remain so for life.

Consent Slip.

I hereby give the Medical Officer of Health or his representatives permission to carry out all the following procedures should he consider them necessary for the protection of my children against diphtheria—namely :—

1. The Schick test.
2. A course of three protective injections.
3. A final Schick test and protective injection after an interval of six months.

Date.................. Signed..........................

A leaflet and consent slip was taken home by each child under 10 years of age with the request that the latter should be signed and returned by a certain day, two or three days being judged ample. A list of children for whom consent had been obtained was then very kindly made out by the school staff giving the name, age, address, and previous diphtheria history of each child. The necessity of adhering to the order of the list in marshalling the children before us on our various visits was emphasised, as thereby much confusion and delay was avoided. On completion of the list it was forwarded to the Public Health Department where a duplicate copy was made in a book which accompanied us on all our visits, and in which all observations were entered. Mutually convenient dates and hours were then arranged for the four to six necessary visits. Facilities were given to the parents to be present on the first occasion, at the test, when the technique was demonstrated and questions invited. At succeeding visits only those parents who had brought under-school-age children to the school for treatment were permitted to be present while the children were being injected.

On the day of the test the children were marshalled by the school staff in one or two queues varying with the number of operators present. The responsibility for the correct children being tested rested with the school staff. A large room with a good light and two doors was usually obtained. It is of great advantage to avoid confusion, to have a separate entrance and exit. Two or more teachers were usually placed at our disposal. Whilst one very efficiently cleansed the arms with spirit, the other stood by the operator checking off each child as it was dealt with, whilst a third, if available, saw that the children who had undergone treatment returned to their respective class-rooms. This procedure was adhered to on successive visits. To complete the work four or five visits were required extending over a period of from 22 to 29 days.

At the first few schools six visits were paid in all but latterly we have cut this down to five, or even four, with equally satisfactory results by reading or the eighth day and giving the first immunising dose at the same visit. Our present time-table is as follows:—

Day.		
1st	..	Schick test.
8th	..	First reading and first toxin-antitoxin injection.
15th	..	Second reading where necessary and second toxin-antitoxin injection.
22nd	..	Third toxin-antitoxin injection.
29th	..	Final visit where necessary to complete absentees.

This time-table has the added advantage of making all visits on the same day each week, thus tending to lessen mistakes as to dates. It was found that where the organisation was very efficient, and an uninterrupted flow of children brought to the skilled operator, that the Schick test (without control) could be applied single-handed to from 100 to 120 or even more children within the hour. As an average, we might count on 100 tests per hour per operator. The immunising injections can be performed with at least equal rapidity. At any one of the various schools two skilled operators were found sufficient to deal with the number of children involved. The time actually spent at the school at any one visit rarely exceeded two hours.

Particulars of readings and dosage of toxin antitoxin mixture were entered in the day-book whilst actually examining the children. At the Public Health Department these particulars were copied on to record cards which were indexed. We are indebted to Dr. Ker for the type of record card which has been found very satisfactory.

Record Card: Headings.

NAME...................... AGE.......... SEX..........

ADDRESS..

Protected—Date	SCHICK TESTS.		
Dosage	Date.	Result.	Pseudo.
Subsequent History :			

All notified cases of infectious disease for removal to the City Hospital are daily investigated in this card index and, if any should have undergone the Schick test, full particulars are forwarded to the hospital. The advantage of possessing this information in regard to patients admitted to an infectious diseases hospital is obvious. Should diphtheria occur in a person who has been tested, the fact is noted on the record card, under the heading "subsequent history."

Technique Employed.

In many of the children under 5 years of age the Schick test was dispensed with, and the child immunised straight away. In children between 5 and 10 years of age the Schick test was always applied, but without a control. We were led to dispense with the control test, available staff skilled in the technique being very limited, by the observation of Ker and McGarrity,[3] who found that among hospital cases only 3·1 per cent. of Edinburgh children between 5 and 10 years of age, mostly scarlet fever patients, gave a pseudo-reaction. There is thus a possibility that three children in every 100 have been wrongly classified as susceptible, and have thus undergone unnecessary immunisation. Nor, unfortunately, was the control test applied to those school-children from 10 to 12 years of age who for one reason or another crept into the scheme. In older children and adults, dealt with at various institutions, the test was invariably controlled.

The uncontrolled testing of children between 5 and 10 years of age has worked on the whole quite satisfactorily, but leaves the operator in a quandary on certain occasions as to whether to class a child as susceptible or otherwise, with the result that the child must be given the benefit of the doubt. This may account for the somewhat higher percentage of susceptible children we have found in this age-period—namely, 64·2, as compared with the figure of Ker and McGarrity—viz., 58·4. In carrying out the re-tests the control test is essential.

All the Schick test toxin and toxin-antitoxin mixture used was prepared by Dr. O'Brien, and supplied from the laboratories of Messrs. Burroughs and Wellcome. The dose given of the former was in all cases 1/50 of the minimum lethal dose for the guinea-pig injected in 0·2 c.cm. of normal saline; the dose of the latter was 1 c.cm., and the full immunising course consisted of three such doses at weekly intervals.

The test was performed on the left forearm. A 1 c.cm. all-glass syringe graduated in 1/20th c.cm. fitted with a No. 214 rustless needle gave a very accurate technique. The toxin-antitoxin mixture was injected subcutaneously about two inches above and behind the elbow. The first and third immunising doses were given into the left arm, and the second into the right. A 5 c.cm. record syringe, fitted with a fairly large bore needle, was found very expeditious and convenient to handle. The skin was cleansed with spirit. The needles were dipped in alcohol between each injection. In some 4000 tests and 6080 injections of toxin-antitoxin mixture no case of sepsis arose.

Number of Consents Obtained.

In Table I. the 16 schools are arranged according to the social status of the scholars, two fee-paying schools heading the list, and two schools attended by the poorest class children occupying a position at the bottom of the list. The intervening schools are attended by a mixed class of children. I am indebted to Dr. Robertson, for many years medical officer of health of Leith, for the above classification of schools according to social scale. The list does not profess to indicate fine differences between school and school.

TABLE I.—*Consents Obtained at 16 Board Schools.*

School.	No. of children under 10—		School.	No. of children under 10—	
	At school.	Consent obtained.		At school.	Consent obtained.
		%			%
A	57	49 (86·0)	I	259	147 (56·7)
B	473	266 (56·2)	J	386	110 (28·5)
C	182	121 (66·5)	K	456	227 (49·8)
D	457	348 (76·1)	L	311	34 (10·9)
E	484	217 (44·8)	M	340	130 (38·2)
F	465	190 (40·9)	N	500	178 (35·6)
G	537	244 (45·4)	O	602	168 (27·9)
H	584	246 (42·1)	P	480	107 (22·3)
Total ..	..	..	.. .. ..	6573	2782 (42·3)

Table I. lends support to the view that the more enlightened the population we have to deal with, the greater response are we likely to get to new preventive methods. The very low figure of 10·9 per cent. for one school can be explained by the fact that this school is attended by children from an old fishing community very conservative in their ideas and very suspicious of new methods. In the case of School D the percentage (76·1) is the result of two opportunities having been given to the parents. At the first canvass, in January, consent was obtained for almost 50 per cent. of children attending school under 10 years of age. On a second opportunity being given four months later, permission was obtained for no less than 53 per cent. of the children under 10 years of age whose parents had hung back on the first occasion. This result is very encouraging, and suggests that when the methods employed are more widely known, and confidence established in their freedom from unpleasant reactions, more and more parents will avail themselves of the opportunity presented to them.

The fact that consent was obtained for 42 per cent. of 6573 board school children between 5 and 10 years of age should help to remove, to some extent, that feeling of doubt regarding the application of new preventive measures to the general population.

Children Under 5 Years and Over 10.

An endeavour was made to get at the pre-school age by inserting a clause in the information leaflet stating that younger children should be brought along to the school for treatment. It is a matter of regret that the parents of only 141 children under 5 years of age availed themselves of this opportunity. Other methods of approaching the pre-school population must therefore be devised.

Although we endeavoured to confine the preventive work to children under 10 years of age, in a considerable number of cases parents were so desirous of having older children tested, and immunised if necessary, that no less than 176 children between 10 and 12 years of age have crept into our records. It is among this group that the Schick test without a control gave rise to real difficulty in reading.

Consents, Tests, and Readings.

It is one thing to obtain consent, but quite another matter to carry through to a satisfactory conclusion at a school the various procedures necessary for the immunisation of the child. Out of 3099 children from 1 to 12 years of age for whom consent was obtained at the 16 schools, 2992 were actually tested, and of these, satisfactory readings were obtained for 2925, or 94·4 per cent. of the original consents. A wastage of 5·6 per cent. occurred, which was accounted for mainly by absenteeism.

Schick Test Results.

In all, 3457 adults and children have been tested since November, 1923, of whom 2925 have been school-children, and 532 inmates of various institutions, excluding the City Hospital. Table II. gives the results of all the 3457 tests made.

TABLE II.—*Total Cases in Schools and Institutions (November, 1923, to June, 1924).*

* For comparison the results of 1540 tests performed on patients at the City Hospital from 1 to 20 years of age by Ker and McGarrity have been put in this column.

There is a very close approximation of our results to those obtained at the City Hospital. The difference of 5 per cent. in the 5–10 age-period may be accounted for by the fact that our readings, owing to the lack of a control test, were always liable to err on the positive side, and hence our susceptibles are probably too high by some 3 to 4 per cent. The diminution of susceptibility as age advances is evident in the table.

Table III. gives the Schick results obtained at 16 schools, and indicates how susceptibility varies not only with age but with social conditions.

The schools are arranged as before in descending social scale. The numbers in brackets recorded in the 1–5 and 10–12 year columns indicate the number of children on which the percentage figure is based.

The same social variation among New York school-children has been demonstrated by Zingher,[4] the generally accepted explanation being that children of the poorer classes, where overcrowding is a marked feature, are much more exposed than the children of better-class households to small and repeated doses of the diphtheria virus, insufficient to give rise to the actual disease, yet effective in producing an active immunity.

TABLE III.—*Schick Test Results in 16 Schools.*

School.	Total number of children tested.	Per cent. of susceptible children at different age-periods in years.		
		1–5	5–10	10–12

P	104	—	34·0	33·3 (9)

The following results obtained at a children's hospital are also suggestive of the part played by the social factor in the development of immunity. Forty-three of the nursing staff between 18 and 25 years of age were tested, and 58·1 per cent. were found susceptible, whilst in 11 maids of the same age-period the susceptibility was only 45 per cent. I might mention here that the entire medical and nursing staff of this hospital, 57 in number, showed a percentage susceptibility of 49·1. This figure approximates very closely to the 50·5 per cent. of susceptibles found by O'Brien[5] and his fellow-workers in the nursing staff of a London teaching hospital.

Familial Incidence.

Zingher[6] noted the marked tendency for all children of the same family to give a similar Schick reaction, either all positive or all negative. When the reactions vary, the younger children, as a rule, give a positive reaction and the older a negative. The results set out in Table IV., obtained during the investigation of 600 families, each of two to five members, lend strong support to the above view.

TABLE IV.—*Familial Incidence of Susceptibility to Diphtheria as Indicated by the Results of the Schick Test.*

Total number of families tested	600
Number of families whose members all gave a negative Schick test	143
Number of families whose members all gave a positive Schick test	280
Number of families in which the younger members gave a positive Schick test and the older members a negative Schick test	126
Number of families in which the younger members gave a negative Schick test and the older members a positive Schick test	51
Percentage of families whose members are either (1) all immune to diphtheria, (2) all susceptible to diphtheria, or (3) in which the younger members are susceptible and the older members immune to diphtheria	91·5
Percentage of families in which the younger members are immune and the older members susceptible to diphtheria	8·5

Does One Attack of Diphtheria Confer a Lasting Immunity?

Of 245 children who gave a history of having suffered previously from diphtheria, 118, or 48 per cent., were Schick-positive. This percentage approximates very closely to the 46·4 per cent. of susceptibles found by Ker and McGarrity in 157 patients with previous diphtheria history.

Active Immunisation with Toxin-Antitoxin Mixture.

The mixture used, the dosage, and the method of administration, have already been described. In

Table V. is shown the number of susceptible children at different age-periods at the 16 schools who were either completely or partially immunised, or escaped immunisation entirely.

TABLE V.—*Immunisations at 16 Board Schools.*

Age-period in years.	Number of susceptible children—			
	Completely or partially immunised.			Who escaped immunisation.
	3 c.cm.	2 c.cm.	1 c.cm.	
1– 5	90	3	10	7
5–10	1545	52	64	37
10–12	92	3	5	—
Totals ..	1727 (90·5 %)	58 (3·1 %)	79 (4·1 %)	44 (2·3 %)

It is very reassuring to note that no less than 92·6 per cent. of those children who received one injection completed their full course. One may assume from such a result that reactions following the toxin-antitoxin injections could not have been numerous, or, if so, were certainly not severe in type. Of the 181 partially or non-immunised children, 94 are accounted for by absence, 5 had left the school, 4 were too nervous, and 78 were due to withdrawal of consent by the parents. Of these 78 children, in 12, for no obvious reason, consent was withdrawn previous to immunisation. Forty-one withdrawals of consent occurred after the first injection of toxin-antitoxin, and may be ascribed to varying degrees of reaction. In the remaining 25 children, consent was withdrawn after two injections had been given. Excluding the 12 children who were withdrawn previous to immunisation, we find that the parents of 66 children refused to permit completion of immunisation, a percentage of 3·4.

In many cases I was able to satisfy myself that the reactions, the occurrence of which had been given as a reason for refusal to permit further injections, were very trifling.

Reactions following Toxin-antitoxin Injections.

In the 160 children under 5 years of age who have undergone immunisation the almost entire absence of reactions was a very satisfactory feature.

In carrying out immunisations at the schools it was not possible to observe the children daily, hence a correct estimate of the number of children in whom definite reactions did occur was very difficult to arrive at. We can, however, definitely state that no serious or permanent ill-effects were produced in any one of the 1864 school-children who were injected with toxin-antitoxin mixture. The same statement holds good for the 240 immunisations performed in various institutions.

Complaints from the parents of 28 children reached our ears. This number amounts to 1·4 per cent. of the total number of children injected. We were able to satisfy ourselves in many of the cases that the general reaction had been trifling, or even absent, and that the rather fearsome redness at the site of the injection had naturally rather worried the anxious parent. In other cases, however, a more or less marked general reaction, necessitating confinement to bed, had occurred. These unpleasant effects were confined mostly to the group of children between 10 and 12 years of age.

In one institution the cases were observed daily after the first toxin-antitoxin injection, and clinical symptoms noted. The particulars are given in Table VII.

TABLE VII.—*Reactions following First Injection of 1 c.cm. of Toxin-antitoxin Mixture.*

Age-period in years.	Number of children who received the injection.	Reactions: Headache, anorexia, and local—	
		With temperature.	Without temperature.
5–10	41	1 (100° F.)	3 (symptoms very slight)
10–15	51	9 (99·4° to 101° F.)	4 (moderate or slight)

In the 5–10 age-group the temperature persisted less than 24 hours in the one case. In the 10–15 age-group the temperature remained elevated less than 24 hours in two cases, 24–36 hours in one case, and 36–48 hours in six cases. All the children had apparently perfectly recovered by the fourth day. The reactions following the second and third doses were not so marked, and the children were able to follow their usual routine.

Effects on School Attendance.

The Schick test, as was to be expected, gave rise to no interference with school attendance. The amount of school time lost, ascribed to the effects of the injections of toxin-antitoxin mixture, varied to an extraordinary degree in different schools—the better class schools tending to have fewer absentees than the poorer class schools.

In some seven schools an endeavour was made to arrive at the number of children whose absence was due to the effects of the injections.

In school C, out of 104 children immunised, there were two absentees who were each away three days. There was good evidence to show that both these children of 9 years of age had suffered from genuine reactions, and had each been kept in bed two days. This gives an absentee percentage of under 2. At school K there were 3 per cent. of absentees following the first toxin-antitoxin injection.

In school O a very different state of affairs occurred. Out of 95 children immunised, no fewer than 52 absented themselves for varying periods of time after the injections—a percentage of 54·7. The total school time lost was 72 days.

In schools A and B absentees were very few in number, whilst in schools I and J 27 and 16 per cent. of the immunised children were absent after one or other of the injections.

It is difficult to believe that such a variation in the percentage of true reactions can occur in children of the same age-period.

Development of Immunity.

In routine school work re-tests are not being performed until an interval of at least six months has elapsed since the completion of immunisation. As it will be several months yet before re-tests can be carried out on the majority of the 2000 children immunised during the first half of this year, we shall have to deal with this aspect of the subject more fully at some later date.

Previous to the re-test being applied, it has been thought advisable to issue the following notice to the parents.

Re-test Notice.

> By the application of the Schick test your child was found to be susceptible to DIPHTHERIA and duly received three protective injections.
>
> A sufficient interval of time has now elapsed to allow for the development of protection.
>
> Before we can definitely state the child is protected against DIPHTHERIA a final Schick test must be applied. This final test is now to be carried out.

In one institution we had an opportunity of carrying out re-tests at varying intervals of time on a group of 91 immunised children. Table VIII. shows the rate of development of immunity.

Out of 92 susceptible children from 5 to 15 years of age 84, or 91·3 per cent., developed immunity to diphtheria within five to six months of completion of immunisation. In the remaining eight children the Schick reaction was less marked than that given by the original test, being classified as faint positive in six and moderate positive in two. A fourth injection of 1 c.cm. of toxin-antitoxin mixture was administered to seven of these children, and on a re-test being applied some two months later it was found that all gave a negative Schick response.

TABLE VIII.—*Development of Immunity.*

Age-period in years.	Number of Schick positive children injected with 3 c.cm. toxin-antitoxin mixture.	Number who became Schick negative within—		
5–10	41	10 wks. : 26	18 wks. : 34	26 wks. : 38
10–15	51	8 wks. : 30	15 wks. : 43	21 wks. : 46

In another group of 29 immunised children and adults (2) only 13, or 44·8 per cent., had developed immunity within a period of five months. The original Schicks in this particular institution might be described as brilliant, and the diminished reactions in the remaining 14 positives (two had left) was a noticeable feature—five being described as faint and nine as moderate positive.

In a group of 155 school-children from 5–11 years of age who completed their full immunisation course six and a half months ago, a recent re-test showed that 66, or 42·6 per cent., had developed immunity. Of the 89 who still showed evidence of susceptibility, 53, or 34·2 per cent., gave a faint Schick reaction and might be termed border-line cases, whilst 36, or 23·2 per cent., were still definitely susceptible.

At first sight the low immunity percentages of 42 and 44 are very disappointing, and not what one has been led to expect from the experiences of other workers. It is highly probable, however, that it is only a matter of time before the border-line cases, some 34 per cent. in the latter group, also show a negative Schick reaction, and were one to re-test again six months or one year later, a much more satisfactory immunity result would be obtained.

Since writing these lines Dr. Ker has very kindly drawn my attention to a recent publication of Zingher and Park,[7] in which they emphasise the great importance of the time factor in the Schick re-test. They found that more than half of those who were still susceptible at the end of three to six months gave a negative Schick reaction one year later without having received any further injection of toxin-antitoxin.

The variation in the immunity results indicates that either the toxin-antitoxin mixture used varied in potency, or that in individual groups of children there are marked differences in the power of response to the toxin-antitoxin stimulus. Whatever the part played by the former, our results seem to indicate that the latter factor is certainly an important one. It is reasonable to suppose that the tuning up of the tissues to respond to the toxin-antitoxin stimulus is produced by exposure of the child to repeated subinfective doses of the diphtheria virus. Should this be the case we would expect to find a better immunity response to toxin-antitoxin injections in a group of children who show a low susceptibility rate than in a group with a high susceptibility rate.

In the institution where the immunity rate of 91 per cent. was obtained the original percentage of Schick positive reactors was 49, whilst in the two groups of children with immunity rates of 43 and 45 per cent. the Schick positive reactors amounted to 73 and 66 per cent. respectively. Our results to date indicate that in a relatively susceptible population with comparatively low diphtheria incidence, such as we have to deal with in Edinburgh, the primary course of three toxin-antitoxin injections will not suffice to produce immunity within six months in a large number of cases, and at least one additional injection will have to be given. The original consent slip has now been altered to provide for this contingency.

Issue of Certificates.

One or other of the certificates here shown, modelled on those at present being used by the New York Department of Health, are issued to parents as the occasion requires: (1) Diphtheria Protection Certificate (A and B); (2) Diphtheria Vaccination Certificate.

Diphtheria Protection Certificates. (A).

This is to certify that......................Age......
residing at......................is naturally protected against DIPHTHERIA as shown by the Schick test performed on......................192....at..........
Issued by..............................
Date..............................

(B).

This is to certify that......................Age......
residing at......................has received protective injection against DIPHTHERIA and is protected against the disease, as shown by the Schick test performed on ....192......at..........................
Issued by..............................
Date..............................

Diphtheria Vaccination Certificate.

This is to certify that......................Age......
residing at..................................has received three protective injections of toxin-antitoxin against DIPHTHERIA. The final DIPHTHERIA PROTECTION CERTIFICATE will be issued after an interval of six months has elapsed, *providing* the child undergoes a Schick test and shows a negative Schick reaction.
Issued by..............................
Medical Officer
Date..............................

Summary.

When an opportunity was presented to the general population of having their children protected against diphtheria, the parents of 42 per cent. of children under 10 years of age attending 16 board schools availed themselves of it. A better response was obtained from the more educated classes of the community. An effort to reach the 1–5 age-period through the various schools has not met with the success one would have desired.

From an analysis of 5000 tests one may expect to find that on an average some 75 to 80 per cent., 60 to 65 per cent., and 50 to 55 per cent. of lower middle and poor class Edinburgh children at the age-periods 1–5, 5–10, and 10–15 years are susceptible to diphtheria. Dispensing with the control test in children under 10 years of age has not given rise to any serious difficulties, and where skilled staff is limited, and numbers to be dealt with very great, is a measure well worth serious consideration. In the re-test, following active immunisation, the control test is indispensable. Susceptibility to diphtheria tends to decrease (1) as age increases, and (2) as we descend in the social scale. In 91·5 per cent. of 600 families all the members either gave the same Schick reaction, negative or positive, or if they varied the younger members gave a positive and the older members a negative reaction.

Almost one-half of those who have had an attack of diphtheria remain susceptible to the disease as evidenced by the positive Schick reaction. Nine-tenths of some 2000 susceptible children completed the full immunising course of three toxin-antitoxin injections. No alarming or permanent ill-effects were produced in any one of the 2104 children and adults immunised. Absenteeism ascribed to the effects of toxin-antitoxin administration varied to a remarkable degree at different schools, being more in evidence in the poorer class schools than in the better class schools. In different groups of originally Schick positive children, from 41 to 91 per cent. developed immunity within five to seven months of completion of a course of three weekly injections of 1 c.cm. toxin-antitoxin mixture.

There are indications that a better immunity result following toxin-antitoxin administration is likely to be obtained in a group of children where positive Schick reactors are few in number and the reactions faint or moderate in intensity, than in a group where positive Schick reactors are numerous and reactions brilliant. In the latter group either a longer period of time than six months will have to be allowed for the development of immunity, or else the primary immunising course will have to be supplemented in a very considerable number of cases by one or more injections of toxin-antitoxin mixture some months later.

We beg to thank Dr. C. B. Ker, the superintendent of the City Hospital, not only for much helpful advice, but also for very kindly placing at our disposal on various occasions members of his resident medical staff. Among the latter, all of whom did excellent work, it may be invidious to mention any one in particular, but to Dr. McGarrity, the senior resident medical officer, we are particularly indebted.

Dr. T. Y. Finlay, child welfare medical officer, very kindly coöperated in the work carried out at the Children's Hospital and various child welfare centres.

Lastly, we desire specially to acknowledge the courtesy and invaluable assistance afforded us by the teaching staffs of the various schools.

THE SENSORY NERVE FIBRES OF THE HEART AND AORTA

IN RELATION TO SURGICAL OPERATIONS FOR THE RELIEF OF ANGINA PECTORIS.

BY J. N. LANGLEY, F.R.S.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF CAMBRIDGE.

Sir James Mackenzie, in an article in THE LANCET [1] a short time ago, has criticised from a clinical point of view the surgical operations which have been performed in cases of angina pectoris. All operations in which nerves are cut are a balance of loss and gain, and as long as there is a chance of relieving the pain of angina pectoris, operations will no doubt be performed. What I wish to point out is that the operations as they have been conducted are open to grave criticism from the point of view of physiological experiment.

The aim of the operations has been to cut those nerves of the heart, or of the heart and aorta, which are capable of giving rise to pain, though occasional reference has been made to the effect of other kinds of afferent fibres. The presence of most classes of afferent fibres in a nerve can be determined by stimulation of its central end. Nerve fibres causing pain cause reflex movement, pressor and depressor vascular fibres are shown either by their effect on general blood pressure or by their local action; the presence of nerve fibres having a special action on inhibition or acceleration of the heart, respiration, contraction, or inhibition of particular organs, are disclosed. Conversely, the absence of any particular reaction shows the absence of a particular kind of nerve fibre. In the intact animal the reactions are complicated by pain, but pain can be abolished by decerebration or by anæsthetics, and the essential nature of the afferent fibres can be more clearly distinguished; pain fibres still cause reflex movement, the depressor nerve causes a fall of blood pressure, and so on.

The theory on which most of the operations have been made is that a considerable number of the sensory fibres of the heart pass to the central nervous system by way of the cervical sympathetic and of the vertebral nerve. This theory is based on the experimental results obtained by François-Franck[2] in 1889. He stated that stimulation of the head end of the cervical sympathetic and of the cervical end of the vertebral nerve caused marked reflex movements. In the course of investigations on the sympathetic system, I made observations on the afferent nerves of the thoracic viscera which, I think, showed that the reflex effect obtained by François-Franck from the cervical sympathetic was caused by attached vagus fibres, and that the reflex effect obtained by him from the vertebral nerve was caused by a small spinal nerve branch accompanying it near the ganglion stellatum. My experiments were made on cats anæsthetised with chloroform and ether. As nearly all were published a good many years ago,[3] I may give a brief account of them here.

In the cat, the chief sympathetic nerves of the heart (and other thoracic viscera) proceed from the ganglion stellatum (the combined inferior cervical and first thoracic ganglia of man). Stimulation of the peripheral end of this nerve causes marked quickening of the heart beat, and in consequence it is called the accelerator nerve. We may call it the major accelerator nerve, since some accelerator nerve fibres pass to the heart by way of the annulus of Vieussens and the inferior cervical ganglion (middle cervical ganglion of man). These nerve fibres may run in more than one nerve strand; we may call the strand or strands the minor accelerator nerve. It contains also the sympathetic fibres (if any) proceeding from the cervical sympathetic to the heart. In different mammals there is considerable difference in the position of the ganglia, in the place of separation of the nerve branches, and in their number and plexus formation, but no essential difference has been found, and there is no reason to doubt that the arrangement in man is essentially the same as in the cat.

Most of my experiments on the major accelerator nerve were made in the following way. The nerve and the sympathetic trunk below the fifth thoracic white ramus were cut. The white rami were cut successively and the central end of the accelerator nerve stimulated after each section. As long as any one of the first five white rami were intact the stimulation caused reflex movement; when all were cut, no reflex movement was obtained. It was clear, then, that sensory fibres of the major accelerator nerve entered the cord by the first five white rami, and that none, or at any rate no appreciable number, took the course of the vertebral nerve and the lower cervical spinal nerves. A few experiments were made on the lower thoracic white rami, and I concluded that the sixth white ramus also contained some of the sensory fibres, but the exact lower limit of origin I left for a future investigation, and this has not been carried out.

The minor accelerator nerve usually contains some fibres from the vagus, and the simplest way of determining its connexion with the thoracic and lower cervical spinal cord is to stimulate the central end of the annulus of Vieussens, which is its only connexion with this region. My experiments on this nerve were few, but in these it was clear that no sensory fibres passed from it to the vertebral nerve, and as far as they went they showed that the sensory fibres arose from the same thoracic roots as those of the major accelerator.

The conclusion that the vertebral nerve caused no reflex movement made it necessary to investigate the cause of the reflex movement which had been described as occurring when it was stimulated. On dissection, I found that a small nerve from the seventh cervical to the musculus longus colli was attached to the seventh cervical ramus. This nerve readily caused reflex action. When it was separated from the vertebral nerve the vertebral nerve caused peripheral effects but no reflex action of any kind.

The next point to consider is the supposed passage of sensory fibres from the heart to the central nervous system by way of the cervical sympathetic. Since the vagus contains sensory fibres it is necessary, when stimulating the sympathetic, to make certain that it contains no vagus fibres. To this end I isolated the cervical sympathetic and cut through the tissue between the ganglion nodosum and the superior cervical ganglion, leaving the anterior branches of the superior cervical ganglion intact. Stimulation of the head end of the cervical sympathetic caused, then, no reflex movement or other reflex effect. Between the two ganglia there are slender intercommunicating branches, and the vagus sends half a dozen to a dozen nerve fibres to the superior cervical ganglion. When these are not cut, I have sometimes found that the cervical sympathetic causes a brief checking of respiration, but I have not found any reflex head or body movement. As with the vertebral nerve, so with the cervical sympathetic, a reflex movement may be obtained if care is not taken that sympathetic fibres only are stimulated. Not infrequently a small nerve filament is given off by the vagus—usually from the superior laryngeal nerve—and runs with the cervical sympathetic. It corresponds in the main with the depressor nerve of the rabbit; it causes a fall of blood pressure, and, usually at any rate, it causes also marked inhibition of respiration, and, following this, reflex movement, chiefly or solely of the head. The reflex movements which have been described as produced by stimulating the cervical sympathetic were then, I consider, produced by the depressor nerve. It may be mentioned that a few myelinated fibres from the glosso-pharyngeal nerve sometimes enter the head end of the superior cervical ganglion. What becomes of these is not known.

Another form of surgical operation is based on the theory that the pain in angina pectoris arises from the excitation of nerve fibres ending in the aorta. Since in the rabbit the depressor nerve has been shown to send nerve fibres to the aorta, the aim is to cut the depressor nerve. But in the rabbit the depressor nerve has very few sensory (pain) fibres, and they appear to be inconstant, for many observers have found none. If, then, in man the exact homologue of the rabbit's depressor were cut, the section would have very little effect on the pain of angina pectoris unless the centres were very greatly sensitised. But, as I have said, the depressor in the cat has sometimes at any rate an appreciable number of sensory fibres, and this may also be so in man.

Daniélopolu, in a recent paper,[4] suggests that in angina pectoris the nerves cut should be the cervical sympathetic with any cardiac branches it gives off in the neck, the vertebral nerve, and the depressor. The experiments I have mentioned above show, I think, that if all these nerves were cut, no appreciable number of afferent fibres (of any kind) passing to the spinal cord by way of the sympathetic would be severed. Most of the vagus afferent fibres passing from the aorta would be cut, but a very small part (if any) of those passing to the heart.

The cardiac afferent fibres existing in the sympathetic can be severed without interfering with the innervation of the head, neck, or fore-limbs by cutting the major and minor accelerator nerves (most of these are probably in the major nerve), but this would sever also all the known sympathetic fibres both afferent and efferent of the head, lungs, and thoracic part of the œsophagus. From an operative point of view the simplest procedure is to cut the nerves passing medially from the ganglion stellatum, leaving intact the vertebral nerve and other rami communicantes. This, however, severs the sympathetic fibres to the head as well as those to the thorax. In the cat it is a very simple operation, and in those cases in which it has been performed it has not been found to have any fatal effect.

VITAMIN B AND LACTATION.

BY GLADYS ANNIE HARTWELL, D.Sc.

(From the Physiological Laboratory, Household and Social Science Department, King's College for Women, Kensington, London.)

THE question as to what constitutes a suitable diet is one which commands a considerable amount of attention at the present time. Physiologically, we are told that a complete diet should contain protein, fat, carbohydrate, mineral salts, roughage, water, and vitamins A, B, and C. Some physiologists already want to claim the existence of a fourth vitamin, but this has not yet been conclusively proved. The *amount* of each constituent needed for health presents a difficult problem. With regard to carbohydrate, fat, and protein, various proportions are suggested as good dietaries—e.g., Voit gives 118 g. protein, 56 g. fat, 500 g. carbohydrate; and Atwater 125 g. protein, 125 g. fat, and 400 g. carbohydrate. Although there are slight differences, these dietaries agree in the main, and a ration of about 100–120 g. protein per day is found to be satisfactory.

When we come to consider the amounts of vitamins essential for the bodily welfare, we have, at present, no figures on which to base our ideas. It is reasonable to assume that there is a minimum, and if the intake falls below this, abnormal symptoms and disease will result. The literature on this subject is very extensive and a vast amount of work has been done to demonstrate the effects of lack of one or more vitamins. On the other hand, when one wants to consider how much of a vitamin is required for health, there is practically no definite evidence. It is frequently suggested that an "adequate" amount must be taken, but this is of no help to the practical dietitian. It is highly probable that the absence of any real data in this connexion is due to our inability to prepare chemically pure vitamins. The amount of these substances present in foods is usually given as +, ++, &c., but of course this is merely a rough indication of the vitamin content of that particular food. Further, one worker may give the content as + and another as ++, the discrepancies probably being due to different methods of investigation. There is very little research work which throws any light on the exact amount of any vitamin necessary, but Osborne and Mendel[1] have demonstrated that there is a quantitative relation between the vitamin B requirement and the size of the animal. These observers were working on rats, and Cowgill's[2] experiments on dogs afford further evidence in support of this statement. Some experiments of the author's indicate that the requirements of the lactating animal (rat) in respect of vitamin B are far in excess of those of the non-lactating creature. In a previous paper[3] it was shown that an excess of protein in the lactating rat's diet led to the development of abnormal symptoms in the suckling babies, and that the baby rats rarely survived. In a later paper[4] it was pointed out that the abnormal symptoms could be entirely obviated by adding to the mother rat's diet any food rich in vitamin B. Thus it was shown that vitamin B is a very important constituent of a lactating rat's diet. Possibly this is also true of a human mother's diet.

The experiments described below are of interest in that they prove that a diet may be eminently suitable for growth, maintenance, and reproduction, and yet produce harmful results in the sucklings if continued during lactation, in spite of the fact that the mother rat remains well.

Experiments and Results.

(*a*) *Diets used:* (1) 30·0 g. white bread, 3·0 g. food casein, 3·0 g. butter, 0·7 g. salt mixture,[5] water; (2) 30·0 g. white bread, 12 g. food casein, 3·0 g. butter, 0·7 g. salt mixture, water; (3) 30·0 g. white bread, 3·0 gluten, 3·0 g. butter, 0·7 g. salt mixture, water; (4) 30·0 g. white bread, 100 c.cm. whole milk;

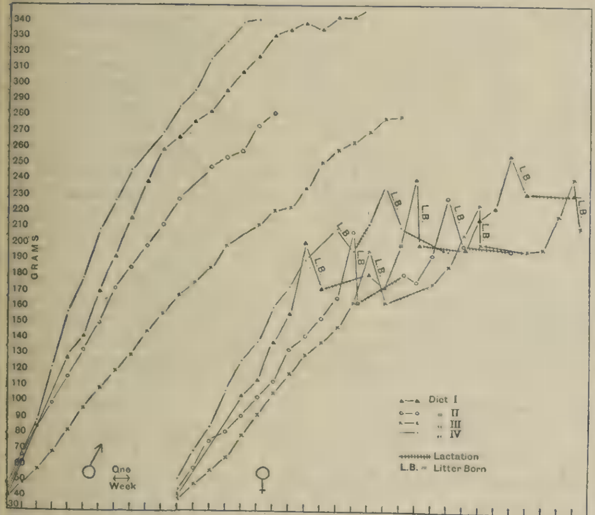
(5) small amounts of bread and milk per day, supplemented by kitchen scraps—i.e., a good mixed diet.

In diets 1, 2, 3, 4 the constituents were well mixed to form a paste, so that the rats could not pick out any one factor. The animals were allowed to eat as much as they liked; they were fed once a day, and the amounts were increased when necessary—i.e., if only a small quantity were left, the ration was increased, all the constituents being increased proportionately.

(*b*) *Method.*—The experiments were started when the young rats were three weeks and two days old. The young are usually weaned at three weeks, and are given a diet of bread and milk for two days, after which they receive the experimental diet. Six males and six females were used in each experiment; they were kept in a cage together, and therefore it was possible for breeding to take place. When a doe was pregnant she was removed from the large cage and placed in a small one by herself, where she remained until the litter was old enough to be weaned (unless she was unable to rear them), when she was returned to the large cage until she again became pregnant. At the beginning of the experiment the young rats were weighed daily, except Saturdays and Sundays, each animal being weighed separately. When they were older and therefore not gaining weight so rapidly, they were only weighed once a week. When litters were born the number of young was reduced to six on the day after birth. The mother was weighed every day and also the litter as a whole.

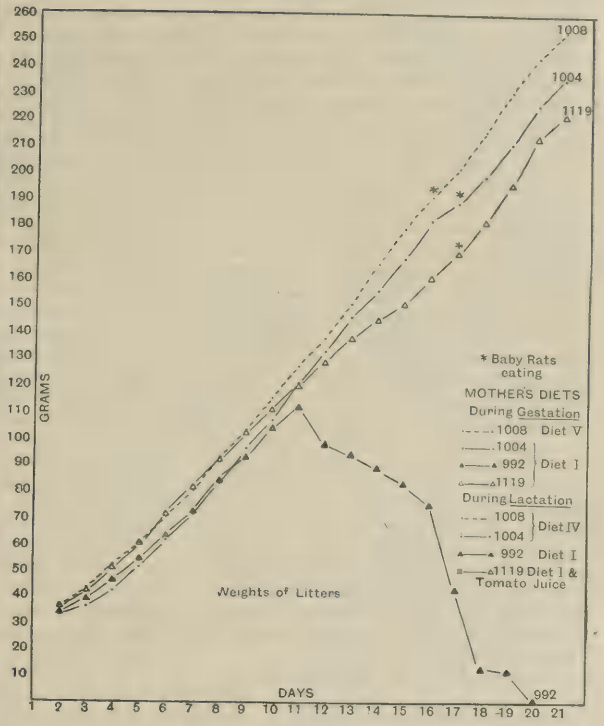
(*c*) *Results:* 1. *Growth.*—The male curves (Chart 1) are taken from the average weights of six animals in each experiment. The female curves represent the growth of individual animals as it was not possible to take an average in this case, because the rats became pregnant at different times. On all three diets, 1, 2, and 3, the young rats grew well and were fit and healthy. In one experiment (diet 1) the feeding was continued for nine months, and this represents a large proportion of the animal's life, because the average age of the rat is 3–4 years. On diet 3 they did less well, probably owing to the fact that gluten is not such a good protein as caseinogen from the growth point of view. (This will be dealt with more fully in a later paper.) On diet 1 the animals showed a growth curve almost equal to that of the control animals, and decidedly better than the normal curve given by other workers—e.g., Donaldson.[6] Thus these diets appear to be satisfactory for the young growing animals and also for adult ones.

CHART 1.



2. *Reproduction.*—Litters were produced at the usual time. The first three does which had litters while being fed on diet 1 were given the same food during lactation, but not one baby survived. They all died, having shown the typical symptoms previously described.[7] The growth curve of the litter of one of the experiments is given as an example (Chart 2, 992). When the next litters were born the mothers were fed on bread and milk (15 g. bread to 50 c.cm. whole milk) and these babies were successfully reared (Chart 2, 1004). This diet was chosen because it has been found to be a suitable one for the lactating rat, probably because it is a good mixed diet as far as the essential physiological constituents are concerned. In some further experiments the mothers were given diet 1 + tomato-juice (6 c.cm. tomato-juice to 15 g. bread, &c.) as soon as the litters were born, and again the babies were successfully reared (Chart 2, 1119). Tomato-juice was used as a source of vitamin B. There is nothing specific about tomato-juice; any extract containing vitamin B was equally effective. In Chart 2, 1008 is the normal growth curve of a litter whose mother received bread and milk during lactation, and a mixed diet of kitchen scraps and bread and milk (i.e., she was a stock animal) during gestation. It will be seen that there is very little difference in growth between 1008 and 1004. This suggests that the diet 1 is quite satisfactory during gestation, but not for lactation. Experiment 1119, and other similar experiments not quoted here, show that diet 1 can be made satisfactory for the lactating rat by the addition of more vitamin B.

CHART 2.



Discussion.

Diets 1, 2, and 3 may be regarded as physiologically complete, with the exception of vitamin C which is poorly represented, if at all. In some earlier experiments it was found that the addition of lemon-juice to such diets made no difference to the growth and condition of the rats, and therefore it has been omitted since. Fat and vitamin A are represented in butter. Bread contains a large amount of carbohydrate, but is low in protein; this factor is supplemented by the addition of more protein, either as caseinogen or as gluten. Vitamin B is present in the white bread,[8] and salt mixture was added to ensure a sufficient supply of mineral salts.

Diet 1 consists of approximately 22 per cent. protein, 12 per cent. fat, 66 per cent. carbohydrate; Voit's dietary gives about 18 per cent. protein, 8 per cent. fat, and 74 per cent. carbohydrate, therefore in comparison diet 1 is richer in protein and fat, and lower in carbohydrate. Atwater's standard diet provides 19 per cent. protein, 19 per cent. fat, and 62 per cent. carbohydrate, and hence contains a far greater proportion of fat than does Voit's standard. Diet 1 is richer in protein than either the dietary of Voit or Atwater, but is possibly more comparable to the diet of the more wealthy classes of human beings, who consume greater quantities of protein than the poorer classes, because protein foods are, as a rule, expensive. Diet 1 appears highly satisfactory for the rat *except* during lactation, and it can be made suitable for that period by the addition of more vitamin B. In other words, it appears that the lactating animal requires a greater supply of vitamin B, or else she is unable to rear her offspring successfully. This point is one which may prove of interest to the medical profession, in that nursing women so frequently cut down the fruit and vegetables in their diet to a minimum. Hence they are obviously lowering their vitamin B intake, since fruit and vegetables are an excellent source of this vitamin.

Diet 2 is much richer in protein and is, perhaps, hardly comparable to the dietary of the average human being, yet it is of interest in that it is like diet 1 in providing for growth and reproduction, but is absolutely unsuitable for lactation. As with diet 1 it can be rendered suitable for the lactating animal by the addition of vitamin B, but because it has a higher protein content than diet 1, still more vitamin B must be added to prevent the occurrence of the bad symptom in the sucklings.

Diet 3 is very similar to diet 1 in composition, except that the protein in this case has a lower biological value, and therefore the growth of the young rats is not so good. Otherwise the experiments gave identical results—i.e., diet 3 provides for growth and reproduction, but the mother rat cannot rear her babies on diet 3 unless more vitamin B is added.

Summary.

Thus, in general, one may say that various diets which are excellent for the growing animal may be totally unsuitable for the lactating animal. In the experiments quoted in this paper, with diets rich in protein, the lactating rat *must* have a greater supply of vitamin B than at other periods of her existence, otherwise she cannot rear her young successfully. If this be true of human beings, a mother taking a diet containing but little more protein than the Atwater standard should include in that diet considerable quantities of foods (e.g., fruits and vegetables) containing vitamin B.

The expenses of this research were defrayed by a grant from the Medical Research Council.

National Maternity Hospital, Dublin.—At the annual meeting of the National Maternity Hospital, held last week, it was stated that 1200 patients had been admitted during the year, and there were 3132 persons treated at the dispensary; 111 students and 75 nurses attended the practice of the hospital. The total receipts exceeded the expenditure by £75. It was pointed out that the present buildings in Holles-street were inadequate for the work of the hospital, and the site gave no possibility of enlargement.

RECENT NEUROLOGICAL THERAPEUTICS.

REGISTRAR, NATIONAL HOSPITAL, QUEEN-SQUARE, LONDON;
AND
E. ARNOLD CARMICHAEL, M.B., Ch.B. Edin.,
RESIDENT MEDICAL OFFICER TO THE HOSPITAL.

Typhoid Vaccine Treatment of Disseminated Sclerosis.

This form of treatment has been practised by us on a series of 70 cases of disseminated sclerosis at the National Hospital during the last 15 months. The idea originated in Vienna, at the Wagner Jauregg Klinik, where it was thought disseminated sclerosis was the result of some intestinal infection. Vaccines of various intestinal bacilli were tried and the most suitable was found to be typhoid. Eight to twelve intravenous injections of the vaccines are given at intervals of one, two, or three days, whichever is most suitable. After each injection one should, as far as possible, obtain a rise of temperature to about 100° F. This rise of temperature takes place within a few hours and then returns to normal within 12 hours. The first dose given is 25 million, and at each successive injection the dose is increased, though if the reaction has been severe from one dose, that same dose should be repeated at the next injection. As much as 400 million has been given in the final dose to obtain the necessary reaction.

This treatment combined with silver salvarsan injections in several early cases brought about a fairly good remission. In the older cases spasticity was slightly reduced, both in the remitting and in progressive non-remitting types of disseminated sclerosis. Two cases of disseminated sclerosis were recently admitted into hospital and treated with typhoid vaccines subcutaneously. The doses given were similar to those used intravenously. Eight were given in each case. No rise of temperature was observed. One of the cases was of the remitting type, the other of the progressive, non-remitting type. Both patients were unable to walk on admission and could not sit up in bed without help. General spasticity was well marked in both cases. The result in these two has been astonishingly good. They can now walk fairly well and spasticity has been much reduced. From these two cases it would appear that a rise of temperature was unnecessary.

As a result of our observations we are of the opinion that this method of treatment offers more satisfactory results than any other recognised method. The usual massage, passive movements, and remedial exercises are combined with this form of treatment.

Sodium Salicylate in Encephalitis Lethargica.

During the epidemic of encephalitis lethargica in the early months of this year several cases were admitted to the National Hospital, Queen-square, for treatment. Owing to the unsatisfactory results obtained by various forms of treatment, such as intravenous hexamine, intramuscular magnesium sulphate, and fixation abscesses, it was decided to attempt the alleviation of symptoms by means of intravenous injections of a solution of sodium salicylate 1 g. being dissolved in 5 c.cm. of normal saline. The injections were given daily for seven days in increasing doses commencing with 0·5 g. of sodium salicylate, and working up to 2·5 g. as a final dose, a total of 10 g. being given. An interval of a few days was then allowed to elapse and the course of treatment resumed. Five acute cases were so treated. Each case varied markedly in type, the following types being represented: myoclonic, excessive drowsiness, peripheral neuritic, and choreiform. Each case showed a marked improvement clinically; the drowsiness subsided; the myoclonic movements rapidly faded away; the pains of the peripheral neuritic type eventually completely disappeared; and the choreiform movements ceased. Three of these cases reported several months later; it was then found that the alleviation of symptoms that had occurred had been maintained and, moreover, that no fresh symptom had arisen.

Stimulated by such results we next treated three cases of the post-encephalitic Parkinsonian syndrome. The results obtained in these cases were undoubtedly less successful, but in two of the cases the ability to write a legible hand returned and the rigidity was definitely reduced. These latter cases we have been unable to follow up.

In assessing the value upon this form of treatment we desire to state that we hold no brief for it as a specific cure. However, it may be justly said that the alleviation of symptoms was highly satisfactory, and that in future one could not say that cases of encephalitis lethargica had been fully treated, as far as present-day therapeutics allowed, unless intravenous salicylates had been given. We are at present using this form of treatment in acute cases of Sydenham's chorea. A further report of its value in such cases will be published at a later date.

Malarial Treatment of General Paralysis of the Insane.

This form of treatment was first systematically employed in 1917 in Vienna, though the method was suggested by Wagner Jauregg as early as 1887. The principle depends on the fact that in chronic disease a remission may occur after the attack of an acute specific fever. Artificially induced benign tertian malaria was found to be the best means of obtaining this fever.

The method of treatment consists in the withdrawal of about 4 c.cm. of blood from a patient suffering from benign tertian malaria who has not been treated with quinine. This blood is injected intravenously, or preferably subcutaneously, into the general paralytic. An irregular temperature is run for a few days to two weeks, when the typical rigors commence. A series of 12 rigors is allowed to take place; the last of this series may occur daily—double tertian. In some cases the rigors may be daily from the beginning. The fever is then terminated with quinine; the first dose of 15 gr. is usually sufficient to prevent another rigor.

Of the cases treated at the National Hospital, a full account of which was published elsewhere,[1] a few cases had remissions. Of the total of 18 cases mentioned in this article, now increased to 24, only two showed remissions comparable to those obtained in Vienna, so that one cannot confirm the optimism of the continental writers. Nevertheless, to obtain a remission in 1 per cent. of the cases of true general paralysis by this treatment warrants its continuance until some better method is found.

Salvarsan injections have been given on the cessation of the fever to improve the anæmia produced by the malaria and to act as an adjuvant to the treatment.

The Tremor of Paralysis Agitans Reduced by Splinting.

In idiopathic and post-encephalitic paralysis agitans the tremor in the hands may be very violent. This can be greatly reduced in many cases by overstretching a group of muscles such as the flexors or the extensors of the hand at the wrist. Radial or ulnar deviation of the hand may give an equally good result. This fact has been utilised by us in cases where the tremor was unilateral and troublesome. A splint was devised of light material with straps and buckles which maintained the hand in ulnar deviation. This could be fixed by the patient himself and could be worn for short periods without much discomfort.

The slight discomfort of the splint was greatly outweighed by the relief gained from a greatly reduced tremor. One post-encephalitic patient with a gross tremor of one hand, as if constantly playing the banjo, obtained much comfort even from a clumsy temporary splint, which maintained the hand in ulnar deviation.

Hypertonic Salines in Cerebral Tumours and Tabetic Crises.

The headache of cerebral tumours is well known to be intractable to practically all analgesics given by the mouth. Henry Cohen reports the use of hypertonic solution given intravenously in six cases of inoperable cerebral tumours. During the last six months we have had the opportunity of treating 12 cases of cerebral neoplasm, two of which proved on operation to be endotheliomata and the remainder gliomata. In each instance 30 c.cm. of a 30 per cent. sodium chloride solution were given intravenously. Following the immediate burning sensation throughout the body, relief of the headache was obtained; but we are unable to confirm Cohen's experience as to the duration of the relief. In all our cases the alleviation of the headache did not last more than 36 hours; hence we have repeated the administration of the solution every second day. On two occasions it was given immediately before operation and proved of undoubted value in lessening the intracranial pressure. In one case it was given after the bone had been removed, and it was evident to all present at the operation that the intracranial pressure rapidly became less, allowing the dura mater to be incised without immediate bulging of brain tissue and its possible consequent damage.

Four patients suffering from subtentorial neoplasms were similarly treated; two of these had a cerebello-pontine angle tumour, one had a large cerebellar cyst lying in the mid-line, and another a tumour of the fourth ventricle. In each of these cases the headache was increased and in one marked quickening of the pulse- and respiration-rates resulted. To explain these results allow us to postulate that the cerebro-spinal fluid is absorbed by the meninges covering the cerebral hemispheres, and that, as a result of the sudden relief of pressure externally, the tumour becomes larger and obstructs the inter-ventricular flow, thereby causing a relative hydrocephalus with its attendant headache. Moreover, as this might institute a herniation of the medulla into the foramen magnum we feel that administration of hypertonic saline in neoplasms of the posterior fossa is fraught with considerable danger.

An acromegalic patient, without enlargement of the pituitary fossa, obtained no relief of the temporal headaches by this form of treatment. Again, the headaches of two cases of pituitary tumour failed to respond to this mode of therapy.

A further extension of the usefulness of hypertonic saline occurs in the treatment of gastric crises and tabetic pains. In four cases suffering from very severe gastric crises hypertonic saline was injected with immediate consequent cessation of the attack. One case with repeated attacks responded three times and then failed to respond again; yet another case attends hospital immediately on the ushering in of a crisis for this treatment and obtains relief consistently. In six cases of very severe tabetic pains immediate relief has always been obtained.

Frequently following cranial operations a degree of œdema of the eyelids may arise which can be immediately reduced by intravenous injection of hypertonic saline. In one case we had the opportunity of watching a papillœdema for one hour after injection of the solution. Six minutes after the injection the height of the swelling was reduced from +5D to +3D, and only returned to +5D 12 hours later.

The following conclusions may thus be drawn: (1) That hypertonic saline given intravenously is of value in relieving headache in cases of cerebral neoplasm, either gliomata or endotheliomata. (2) That an element of danger arises in cases with neoplasm in the posterior fossa owing to a possible hydrocephalus resulting. (3) That gastric crises and tabetic pains may be relieved. (4) That papillœdema and orbital œdema are reduced. (5) That pituitary tumour headaches are not relieved.

Clinical and Laboratory Notes.

A CASE OF CONTRACTED TENDON TREATED BY THE ZANDER METHOD.

BY MAGDA H. HAMEL, M.R.C.S. ENG.

THE problem of restoration of good function in a long-established contracture of a tendon, though happily rarer than of old—owing to generally more efficient primary treatment—still confronts us from time to time, most frequently in the tendo Achillis. I have found that in old-standing cases a simple tenotomy gives less good results than a gradual stretching by mechanical means, of which the Zander machine is the most efficient, overcoming as it does the disuse immobility of the joint while the tendon is being stretched.

The following case, typical of many in which 20°–30° of dorsiflexion have been obtained in the course of some three weeks, was that of a foot with contraction of tendo Achillis following anterior poliomyelitis.

A girl of 21, who had anterior poliomyelitis at the age of 5 years with foot-drop and contraction of Achilles tendon as sequelæ, was sent to me on July 11th by Dr. G. L. Crimp. An Achilles tenotomy was performed three years before this date, but when I first saw the patient her foot could only by force be dorsiflexed to an angle somewhat more obtuse than a right-angle, though prolonged massage and movements had followed the tenotomy. In order to obtain greater flexion prior to a tendon transplantation I used the Zander ankle-machine. This machine, invented by Dr. Gustav Zander, of Stockholm, in 1865, and much more used on the continent than in this country, brings a strong, steady, easily regulated pressure to bear on the joint and tendons, and in my experience is more successful than any other method.

FIG. 1.

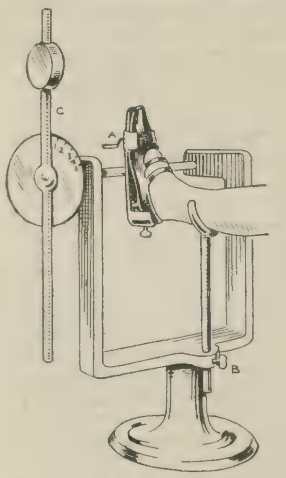

FIG. 2.

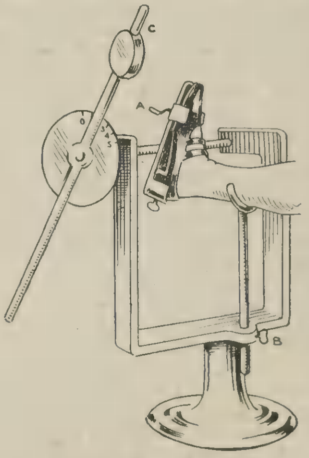

FIG. 1.—Leg placed on Zander machine prior to tendon stretching A, foot clamp; B, leg rest; C, lever, worked by operator.

FIG. 2.—Showing dorsiflexion of foot.

The foot is fixed in foot-clamp A of machine as in Fig. 1; leg-rest B is adjusted, and then the operator gradually pushes over lever C from zero position to points 1 or 2 on the scale according to sensations of patient and "give" of joint and contracted tendons (see Fig. 2). This movement is repeated for 20 minutes on the first day and the point of greatest flexion noted on the scale. On the next day this point will probably be reached quite easily, and a further few degrees of flexion will be obtained on each day of treatment. In this particular case the required degree of flexion was obtained in about three weeks, during which time the patient attended three sessions a week for this purpose, and also for electrical stimulation of the extensor longus hallucis muscle prior to its transplantation into the tendon of the completely paralysed tibialis anticus. Incidentally, after six weeks' treatment, the extensor longus hallucis, from a condition of great weakness, has now reached practically normal contracting power. While on the machine the patient felt not only the stretching of the Achilles tendon but also slight pain over the anterior aspect of the ankle-joint. This is not unusual in such old-standing cases for the reason explained above—i.e., the limitation of mobility due to disuse of the joint. The articular facets of the bones forming the ankle-joint now glide smoothly over a sufficient range to enable transplantation to be successful.

Tenotomy alone can only cure half the trouble in these cases, whereas on the Zander machine the two factors of contraction of the tendon and disuse atrophy of the joint are dealt with concurrently.

MALARIAL THERAPY IN GENERAL PARALYSIS OF THE INSANE.

THE DISAPPEARANCE OF GASTRIC CRISES AS ONE OF THE RESULTS.

BY W. M. MCGRATH, M.B., B.CH., U.C.D.

L.C.C. CANE HILL MENTAL HOSPITAL, COULSDON.

THE gastric crises common in tabes dorsalis, and which occur more often than is suspected in general paralysis of the insane, are exceedingly resistant to ordinary dietetic and drug treatment, so that the cessation of these distressing occurrences in a case of G.P.I., after treatment by malarial therapy, is deemed worthy of note. The only drug which can be relied on to control the vomiting and pain of a gastric crisis is morphine, and tabetic patients are especially prone to contract the morphine habit, while the operative treatment is so severe as only to be warranted in cases of the utmost severity.

The patient, a married man, aged 34 years, was admitted to Cane Hill Mental Hospital on Oct. 3rd, 1923. It is stated that he contracted syphilis at the age of 18, which had been untreated until two years from his certification.

He had been admitted to Charing Cross Hospital on Feb. 17th, 1922, suffering from sudden collapse, fainting attacks, and constipation, and with a history of frequent vomiting for six months—sometimes as often as 30 times in the 24 hours, with free intervals lasting up to seven days. These vomiting attacks were accompanied by severe epigastric pain and occurred independently of food. He had lost 3 st. in weight and was much debilitated. His blood was found to give a positive Wassermann reaction. He was given anti-syphilitic treatment, consisting of mercurial inunction and two injections of N.A.B.

After admission to Cane Hill he had a definite gastric crisis on Oct. 31st, 1923, when vomiting lasted for 36 hours. Further similar attacks were noted on Dec. 4th, 11th, and 22nd. Malarial therapy was started on Feb. 5th, 1924, and towards the conclusion of the treatment he had a further attack of persistent vomiting and epigastric pain. In this instance the vomiting continued for 14 hours. All these attacks of vomiting presented the characteristic features of a gastric crisis—i.e., onset sudden, severe epigastric pain, with repeated vomiting independent of food, a definite girdle of anæsthesia, pallor, and sweating. He tolerated the malarial therapy well and did not develop any complications. Since then he has remained absolutely free from all gastric disturbances of any kind, and has been on full ordinary diet.

While it is, of course, not justifiable to draw conclusions from a single instance, the cessation of these distressing occurrences in this case over a period of eight months makes it probable that this treatment might be worth a trial for severe and frequent gastric crises in an ordinary tabetic. The mental improvement was, of course, the object of the malarial therapy. That this was achieved is shown by the fact that the patient could be discharged as recovered, and it is also highly satisfactory that a physical condition so distressing and recalcitrant to ordinary treatment was relieved at the same time. A series of cases of general paralysis are at present being treated at this hospital and it is hoped, at a later date, to publish a full report.

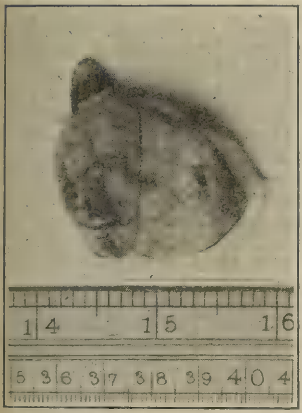
I am indebted to Dr. S. C. Elgee, the medical superintendent, for permission to publish this case, and I thank Colonel S. P. James, of the Ministry of Health, for his help and assistance.

URETHRAL STONE OF UNUSUAL SIZE.

BY JOHN CLAY, C.B.E., F.R.C.S. ENG.,
SURGEON TO THE ROYAL VICTORIA INFIRMARY,
NEWCASTLE-ON-TYNE.

THE unusual features presented by this case are the size of the stone, and what is, perhaps, still more remarkable, the little discomfort it occasioned during its formation.

The patient, aged 44, married, with three children, is a hewer in a coal-mine. Twenty-seven years ago, when a boy of 17, he was crushed between wagon buffers, sustaining a fracture of the pelvis and a rupture of the bladder and urethra. He was operated on by Mr. Page, of Newcastle-on-Tyne, and made a good recovery. He followed his occupation without discomfort until Tuesday, April 22nd, 1924, when he began to suffer from very severe dysuria, and the scrotum began to swell. He attributed the condition to working in a wet part of the mine. On April 25th he was admitted to the Royal Victoria Infirmary, Newcastle-on-Tyne, with retention and signs of extravasation of urine. He was operated on by Mr. Hamilton Barclay, who made a suprapubic cystotomy, and incisions into the extravasation. No instrument could be passed per urethram into the bladder. On May 13th, when examining the patient under an anæsthetic, I was able to feel definite crepitus in the swelling in the perineum, and the mass felt like a stone. I cut down upon it and removed a large stone. The stone (see figure) was $2\frac{1}{2}$ inches by $1\frac{1}{2}$ inches, and it weighed 9 drachms 20 grains. It had evidently fractured, and where the two fragments were in contact there were perfect saddle-shaped surfaces. At the distal side of the part of the urethra containing the stone there was a very fine channel, leading through a short stricture. I opened the urethra distal to this stricture and divided the stricture completely, passed a silver catheter into the bladder, and tied it in. The convalescence was smooth and uninterrupted.



Urethral stone.

I have been unable to find a record of the sizes of stones removed from the urethra, and certainly none of those that I have seen have in any way approximated in size to this. Twice before I have felt crepitus produced by urinary stones. In one case there were many stones in the kidney, and in the other stones in the prostate. So crepitus is a sign that sometimes assists in the diagnosis of stone.

In the course of my work I see many patients who are in receipt of compensation for disabilities, and it is remarkable how slight a defect sometimes renders a man incapable of following his occupation; yet this man, in spite of a very narrow stricture of the urethra, and a stone of this size lodged behind it, was able to continue his work as a coal hewer without even discomfort. The only explanation I can offer is, that there are men whose nervous systems are so constituted that they do not react to injuries and disease to the same extent as others, and it is, perhaps, fortunate for the mining industry that there are many such men.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A MEETING of this section was held on Nov. 5th, when Mr. H. J. PATERSON delivered his Presidential address, which he entitled

The Lure of the New.

[Speaking of the advances of modern surgery, he quoted Huxley's cynical remarks that the "customary fate of new truths is to begin as heresies and end as superstitions," and continued :—]

Nevertheless we are ever seeking new lamps for old. Some of our new lamps have a dazzling brilliance, but their endurance is transient; others shine as beacon lights on the pathway of progress. Although every inventor or originator is not necessarily an Aladdin, he plays a part of supreme importance in surgery, as in every other field of human activity. Whether his ideas be trivial or important, he stimulates thought. Like Lister he may change the whole practice of surgery, or he may merely make some small suggestion which ultimately may prove part of an epoch-making discovery. His new lamps may be useless for the purpose for which they are designed, but in other directions they may prove of extreme value. Sayre's plaster jacket was intended for the treatment of scoliosis. The method was sound, but its application to this particular disease was erroneous, but by drawing attention to this subject, in time it led to the enunciation of the correct principles on which lateral curvature should be treated. The birth of modern intestinal surgery may be attributed to an invention long since discarded, Murphy's button. The introduction of this method demonstrated the possibilities of intestinal anastomosis, and by focusing interest on this subject led to methods which have superseded the use of mechanical appliances.

Not seldom the new lamps given to us by inventors are spoilt by injudicious modifications or improper use. When Sir Arbuthnot Lane introduced his method of plating simple fractures, some surgeons employed it for the treatment of compound fractures, with unsatisfactory and often disastrous results. They were putting a valuable procedure to a use to which its originator stated it was totally unsuitable. I do not suggest that a new invention cannot be improved, but before attempting to make improvements it is wise to ascertain whether our ideas have already been tried without success.

The Disadvantages of Progress.

I think it will be conceded that even the greatest discoveries have disadvantages as well as compensations. The two greatest blessings given to surgery during the past century, anæsthesia and the principles fo asepsis, are not exceptions to this generalisation. Both have tended to prolong operations unnecessarily, so that to this extent they have been harmful, although the sum of the benefits they have conferred is priceless. In pre-anæsthetic days the surgeon tried to complete his work as speedily as possible, because he was inflicting pain. With the introduction of anæsthesia the surgeon could be more deliberate in his methods, and so unconsciously prejudiced the interests of his patients. In this respect the war was a bad training ground for young surgeons. Many long and very severe operations were performed for abdominal injuries, but the natural resistance of the patients was very different from that of the ordinary patient of civil life. In his fascinating Presidential address to this section two years ago, Mr. James Berry emphasised the value to the young surgeon of a thorough training in the making of post-mortem examinations. I would add to this wise advice that, in addition, some experience as an anæsthetist should form part of the training of anyone who aspires to practise surgery. He would learn not only many useful surgical lessons, but he would understand more of the shock produced by operations. The drugs used to induce anæsthesia are highly toxic, and we are apt to forget that apart altogether from the effect of the operation, the anæsthetic has also a harmful influence on the patient. Every experienced anæsthetist knows that even the strongest patient begins to flag perceptibly after an hour, and after an hour and a half this change is still more accentuated. Dr. R. T. Morris, of New York, relates how a house surgeon who had served under two surgeons of about equal capability was asked his reason for the difference in their statistics. His reply was "About ten minutes." There is a wealth of wisdom in this seeming exaggeration. The expert anæsthetist, not being a politician, keeps our patients in such a state of tranquillity that we are tempted to be almost too deliberate, and to forget the importance of rapid, or rather expeditious operating. Let us each ask ourselves whether our technique may not be simplified without loss of efficiency. We must not make a goddess of technique and forget that it is of no less importance to assist nature by conserving the patient's resistance. In our attempt to secure perfect asepsis we may so prolong the operation that the patient's chances of recovery are prejudiced. Better incomplete technique and a live patient than a perfect technique and a dead patient. I am not sure that a good case could not be made against the use of rubber gloves. At any rate, Sir Harold Stiles without them has achieved results surpassed by none. Lawson Tait, too, showed what could be done with a simple technique and expeditious operating. His results were so good that the surgeons of his day took refuge in regarding their accuracy with an attitude of unphilosophic doubt.

[The lecturer then pointed out the danger of "short cuts" as instanced in the practice, largely fostered by war surgery, of omitting drainage of a wound as far as possible. In his experience, excision and primary suture were rarely satisfactory. Passing on to the value of laboratory methods in diagnosis, he emphasised the point that such methods were an aid to, but not a substitute for, clinical observation.]

Intestinal Stasis.

Not one of the least dazzling lamps given to medicine in recent years is the hypothesis that intestinal stasis is responsible for many of the ills to which our flesh is heir. It is alluring in its simplicity and fascinating from the vista of hope which it opens up. It has been given to few to originate two such startling proposals as the operative treatment of simple fractures and the surgical treatment of intestinal stasis, and Arbuthnot Lane has not escaped the criticism and bitter opposition which falls to the lot of all pioneers. Few subjects have excited greater controversy than the statement that intestinal stasis produces toxæmia. It has been assumed that such teaching is unscientific, because we do not know the nature of the toxins produced or even of their existence. This argument need not perturb the seeker after truth. The malaise and debility which accompany tuberculosis were recognised long before the discovery of the bacillus which produces the toxins which are the cause of the constitutional symptoms. This much at least we do know, that patients who are the victims of a disorder which impairs their mental and bodily vigour, which causes such constant discomfort and pain as to reduce them to a state of misery, and which renders them incapable either of work or enjoyment of the pleasures of life, may be relieved by treatment directed to the removal of existing intestinal stasis. This is a truth established by the work of surgeons all the world over. When, however, we consider to what extent surgery should interfere, there is room for wide divergence of view. Whether all Lane's teaching be true or not, time alone can show, but without doubt his lamp has cast light in hitherto dark places, and has led to a new conception of abdominal diseases.

[The lecturer then spoke of the modern tendency towards specialisation in the many fields of modern surgery, and dealt at some length with the relative merits of gastro-jejunostomy and partial gastrectomy in the treatment of gastric ulcer. A battle had been raging between the "ectomists" and the "ostomists," and for the present numerical victory was with the "ectomists," but "safety first" was a good slogan in surgery, and in the hands of the average surgeon partial gastrectomy, as a severer operation, had a much higher mortality than gastro-jejunostomy. Considering the position of surgery as a whole, he said :—]

The Art of Surgery.

It is significant that, in spite of the multiplication of specialities, the general physician and general surgeon in their outlook and attitude of mind are converging rather than diverging. The physician of to-day must be a surgeon except as regards the craftsmanship of their common art, and if I as a surgeon may say so, there are physicians whose surgical judgment cannot be excelled. Equally the modern surgeon, if he is to do his work with satisfaction to himself and with advantage to his patients, must have a wide knowledge of general medicine. He is no longer a carpenter to operate at the behest of another. He is rightly expected to make his own diagnosis and to form his own judgment. Indeed, a surgeon may be defined as a physician who has learned to use his hands. Art has been defined by Ruskin as "the operation of the hand and the intelligence of man together." Surgery is an art, and although, in addition, it is slowly and surely being built up into a science, it seems to me that the science must ever be subservient to the art. With all the aids that modern science can give, there still remains the personal factor, call it judgment, clinical acumen, intuition, or what you will. We must ever be on our guard that our judgment is not warped by the lure of the new. New lamps may add to our light, but they cannot altogether replace the old. The true wisdom of surgeons is experience. As Napoleon so well said : "The world is very old ; so we must profit by its experience. It teaches that old practices are often worth more than new theories."

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

AN ordinary meeting of the Society was held on Oct. 23rd, Sir PERCY BASSETT-SMITH, the President, occupying the chair.

Sir MALCOLM WATSON read a paper, which was profusely illustrated by means of the epidiascope, entitled

Observations on Malaria Control,

with special reference to the Assam tea-gardens ; and some remarks on Mian Mir (Lahore Cantonment).

Sir Malcolm Watson said he recently visited a large group of tea estates in Upper Assam for the purpose of advising on the control of malaria, which was prevalent in the gardens. It was evident to him that the disease was widely-spread throughout Assam, and from this and other causes the death-rate of the workers was high at one time, but the efforts which had been put forth of recent years had made a high death-rate a thing of the past, and the speaker paid a tribute to the medical officers of the gardens for what they had done. He first showed, in illustration of the measures which were effective in reducing malaria incidence, slides explanatory of what had been done in the Federated Malay States. Tide gates were established, and deep drainage of the mangrove swamps was carried out. This, with clearance of the jungle for 20 miles, had resulted in the complete abolition of the disease from the district, and the spleen-rate among more than 900 children was 0·9 per cent. Next, an open drainage system of coastal plains was carried out, and with this and the cultivation of the land, malaria disappeared. In the coastal hills malaria was found due to the presence of *Anopheles umbrosus* where the ravines were covered by jungle, and disease due to *A. maculatus* when the ravines were cleared. The problem was solved by putting the springs and streams into subsoil pipes, and using refuse oil. Since the health officers in Singapore began their work in 1912, it had been computed that they had saved 35,000 lives. Dr. Strickland made the important observation that inland hills which were under the jungle were free of malaria because *A. umbrosus* did not breed in them; only when they were cleared did the district become malarious, and then the disease was due to *maculatus*. In the matter of rainfall and general climatic conditions there was close approximation between Malaya and Assam.

The great physical feature of Assam was a broad flood-plain bounded by high banks and traversed by a winding, flowing river, which, however, formed two loops which became gradually silted up. The original jungle has been cleared away to make room for the rice-planting, and in the uncultivated land merging on this the speaker found *A. maculatus* and *A. minimus* in abundance, and malaria very prevalent. Among 9146 children he found a spleen-rate of 69 per cent. and of 2416 children of 2 years and under 61 per cent., had enlarged spleens. These particular estates were among the richest and best worked in India, and the coolies were well housed. In addition, pregnant women received good care, both before and after confinement, and ceased work during that period. But all the usual health measures failed to prevent infection of coolies by the malaria parasite, though it helped them to acquire immunity, an immunity apparently inherited by the children. Still, 69 per cent. of the children on the estates had enlarged spleens. Nothing short of a direct attack on the mosquito could be expected to stamp out the disease.

One method of controlling the insects was to remove all the coolie lines to a central spot, and to abolish all breeding places of the mosquito within half a mile of it. This would have meant a large sum for removing and rebuilding coolie houses. The alternative was to leave the coolies where they were and strike at the two dangerous species of anopheles: *A. maculatus* and *A. minimus*. Usually he found that the lower and flatter the land, the lower was the spleen-rate, for the higher the land, the better was the opportunity for *maculatus* to breed. In Assam it was in the best and best-managed estates which showed the highest prevalence of malaria. Experience, both that of Gorgas in America and of our own workers in the Empire, showed that ordinary sanitary measures were powerless to prevent malaria; there must be a proper system of drainage to eradicate the breeding places. Sir Malcolm Watson's advice could, therefore, be summarised in a sentence: The establishment of effective drainage, coupled with the administration of cinchona to children and all fever cases. These measures, he said, would soon result in the control of the disease.

From Assam, Sir Malcolm Watson proceeded to the Lahore Cantonment (Mian Mir). In the work carried on there between 1902 and 1908 he thought wrong methods were adopted, but it was the first attempt to control malaria in India, and the irrigation system complicated the problem and confused the issue. Certainly, however, the results expected were not achieved. He had great hopes for a very great diminution in the prevalence of malaria as a direct result of measures such as he had advised and carried out.

Discussion.

The President spoke of the importance, in this work, of intelligent coöperation with the medical officers on the part of the owners of the estates and lands concerned. Sir Malcolm Watson evidently had a large measure of that optimism which was such a factor in success.

Sir Ronald Ross, F.R.S., said the speaker's work had been very great, and he questioned whether either its extent or its importance was adequately appreciated in this country. The great work of Gorgas in the Panama region had the financial backing of the American Government, a very different state of affairs from that associated with Sir Malcolm Watson's work, which started at about the same date, some 25 years ago. The latter had to try to persuade hundreds of people, owners of land and others, to assist in the work, and it was a very difficult matter. The lecturer had shown how necessary it was to deal with the different species of mosquito in different ways; also how supreme was the importance of having no stagnant water about. He hoped the Indian Government would take the matter up energetically, and not allow mankind to be defeated by the mosquito, an insect which killed about two million people per annum. The campaign was not only necessary for the reduction of illness and suffering, but it was also eminently a paying proposition.

Sir William Leishman, F.R.S., said he thought Mian Mir was a much-maligned spot. Thirty years ago he spent three years there, and the British soldier in that place did not die very much from malaria, though the spleen-rates were appalling. Deaths were due rather to dysentery and enteric. In those days the importance of drainage was not realised. He hoped that the Treasury would take careful note of this communication.

Dr. Andrew Balfour said he had listened to the paper with mingled feelings of sadness and pride; sadness that after a quarter of a century of effort such a state of things now existed in India, and pride at the achievement which Sir Malcolm Watson's work had resulted in. There was great need for more apostles of hygiene to be sent out, like Sir Malcolm Watson, to persuade people on the spot to take a hand in their own remedial measures. He insisted on the great potency of soapy water in killing off mosquitoes, and said if this were used it would greatly reduce the still too-high incidence from this disease.

Major E. Austen expressed his pleasure that emphasis had been laid on the importance of biological research in this campaign, for the particular species being dealt with in a region must be known before measures undertaken could be expected to succeed. He agreed as to the destructive effect of soapy water; he had often noticed many dead mosquitoes after soldiers had washed in the water inhabited by insects, and some experiments he made with water from a used bath enforced the same lesson.

Dr. C. M. Wenyon spoke of an occasion when many anopheles and other mosquitoes came on board a ship which was ten miles from the shore. On another occasion, when at the same distance, a number of house-flies, which had been pursued by dragon-flies, reached the ship.

Dr. P. H. Manson-Bahr spoke of epidemics on board liners from the East which had occurred during the last two weeks, in order to enforce the need for a much more energetic dissemination of knowledge concerning malaria in every country. When the P. and O. liner *Macedonia* arrived in English waters she had lost one of her officers from malaria, and when she reached Southampton two of her officers, 20 to 30 of the white crew, and a large number of lascars were admitted to hospital suffering from subtertian malaria, in various stages and of various types. At Bombay the ship had been anchored half a mile from shore, opposite some building operations, where there was a pool of stagnant water. Many of the ship's men slept on board. There was no report of sickness when the ship set sail, and thereafter those whose duties were not the most strenuous carried on, though for ten days they became less and less fit. Then they began to go down one after another, and eventually the struggle had to be given up. Many of the cases were not recognised on the voyage to be malarial at all, and inquiry showed that the amount of quinine given was not enough to control the fever; there was not enough of it, nor was that in stock of the right kind. A similar occurrence took place on other boats leaving the East at about the same date.

Colonel W. W. **Clemesha** related similar experiences at an earlier date, and said that inquiry of an officer who had suffered from inadequate medical attention on several voyages elicited the reply that the medical officers he sailed with were either very young or very old.

Sir **Malcolm Watson**, in replying on the discussion, said it was not an easy thing to educate in these matters those who provided the money. He often remarked that most of his life had been spent not in fighting the mosquito, but in fighting men who were preventing him from fighting the mosquito. A great source of malaria in Bombay was the continuance of the Hindoo well in private houses, and as long as the hands of the Indian Medical Service were tied in that way, real progress would be impossible. He instanced one estate on which £7000 were spent in these remedial measures, and thereafter more than that amount was saved commercially every year on that particular land. He did not think the distance the mosquito could fly was quite the same question as the control of malaria. It could fly half a mile, but if its breeding places were half a mile from a cantonment, the number of the insects which covered the distance and could thereafter infect would prove to be practically negligible. He had carefully investigated that question. If there should be a taxation for the purposes of the campaign, he was sure it would more than justify itself.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Liverpool on Oct. 17th, Prof. **Archibald Donald**, the President, being in the chair.

The **President** opened a discussion on the

Treatment of Mobile Backward Displacements of the Uterus.

He discussed the significance of backward displacement and said that there was a good deal of difference of opinion amongst writers on the subject. The views of various modern writers on the passive congestion theory were set forth. The objections to the congestion theory were that retroversion was *not* the cause of endometritis or chronic metritis. There were some difficulties, he said, in explaining the effects sometimes produced by a pessary. As a result of investigating the symptoms he had arrived at the following conclusions with regard to the condition. (1) Complications were generally the only things that mattered in cases of retroversion. (2) These complications were: (*a*) disordered uterine function; (*b*) increased weight; (*c*) prolapse; (*d*) adhesions. (3) None of these complications were produced by retroversion. (4) In a small proportion of cases an apparently simple retroversion caused local pelvic discomfort and even a certain unexplained effect on the nervous system. (5) The treatment of retroversion was nearly always the treatment of complications. More than 90 per cent. of all the patients sought relief from symptoms which were common to all cases of endometritis and chronic metritis, and for these curetting was nearly always advisable. A series of cases in which curetting had been the only treatment was recorded. Mechanical treatment was carried out (*a*) by pessaries, and (*b*) by fixation or suspension operation. Pessaries seemed of use as a temporary measure in cases of sterility and early pregnancy, and very occasionally in uncomplicated retroversion. In his opinion there were far too many operations for fixing and suspending the uterus. The great majority were unnecessary, and many of them were harmful.

Prof. **Henry Briggs** imagined that a student, ignorant of all gynæcology including its nomenclature, would naturally classify the backwardly-displaced uterus within the pouch of Douglas as a hernia and aim at the strengthening of the deep portion of the pelvic floor and the rectification of the position of the uterus. He said that it was more than singular to have to acknowledge, for example, that the best use of a 3 or 3½-in. ring pessary was advocated 24 years ago by the late Sir William Sinclair (Trans. Obstet. Soc., 1900) in the treatment of the retroflexed gravid uterus; even to-day this advance was not to be found in the obstetrical text-books. Prof. Briggs had not the least doubt that a pessary in situ and frequent urinary catheterism, in gentle and persistent effect, totally out-classed manual reposition.

Dr. G. W. **Fitzgerald** agreed that not all retro-displaced uteri required treatment. Symptoms accompanying the displacement were not necessarily due to it. The important matter was to find what treatment would give the best results. If the curette could show results equal to abdominal section, then the minor treatment was to be preferred. He curetted all cases that produced symptoms, and only rarely found more radical treatment necessary.

Dr. J. E. **Gemmell** said that he was in agreement with Prof. Donald that simple retroversion in single women was symptomless in the majority of cases. In parous women, however, he was of the opinion that this displacement was, in itself, capable of producing a definite train of symptoms. He could not help thinking that there was a world of difference between an organ that was developed in a particular position of version, and one that acquired such a position. The vessels of the former had been congenitally adapted to meet the requirements of the retroverted uterus and could do so smoothly and without embarrassment to the circulation, whilst in cases of acquired retroversion the vessels shared in the displacement and were thereby exposed to abnormal pressures that fell chiefly on the veins and consequently led to back-pressure and congestion. The resulting symptoms *simulated* endometritis and metritis, but he believed they were essentially due to congestion, and he therefore supported the mechanical theory. In his opinion there were three clinical types that demand correction and fixation: (1) In a limited number of congenital cases when the patient complained of sterility, repeated abortions, dysmenorrhœa, or dyspareunia; the type with neurosis and backache was expressly excluded. (2) In obstetric types with the following cardinal signs: a bulky, tender œdematous and often incarcerated (but not fixed) uterus, associated with pain, menorrhagia, leucorrhœa, or dyspareunia. (3) In cases of simple retroversion accompanied with early prolapse in young women of child-bearing age.

Although pessaries and general therapeutic measures were useful adjuncts, and might even be curative in mild cases, he said he wished to limit himself to the surgical treatment by ventrofixation of this condition, and proposed to base his remarks upon 125 cases of simple retroversion that were published in THE LANCET of June 18th, 1921, in collaboration with Mr. Leyland Robinson.

A summary of the results was as follows: 85·6 per cent. cured, 10 per cent. relieved, 4·4 per cent. failures. The principles of ventrofixation, Dr. Gemmell said, were not generally understood, and he believed that this procedure had acquired an unpopular reputation because most gynæcologists had studied the wrong type of operation. The type he and his colleagues had practised was planned to fulfil the three essentials upon which the success of all gynæcological operations depended—namely: (1) Freedom from immediate risks, such as intestinal obstruction; (2) freedom from the risk of interfering adversely with subsequent conception and parturition; (3) ability to relieve symptoms.

The proof that ventrofixation met these requirements was furnished by the following facts: (1) Of upwards of 700 ventrofixation operations performed by him, one patient died from sepsis under circumstances that had nothing to do with the operative procedure. There were no examples whatever of post-operative strangulation of gut. (2) Of 220 cases in which a complete after-history was obtained, 63 women subsequently became pregnant and were safely delivered of 104 children without a single case of dystocia or stillbirth. (3) The effect of ventrofixation on symptoms had already been dealt with (85·6 per cent. cures).

Successful operative technique depended upon three chief factors: the choice of a suitable fixation-point; the prevention of adventitious intraperitoneal bands and holes through which the gut might strangulate; and the achievement of a fibromuscular fixation and not of a peritoneal suspension.

Mr. W. GOUGH agreed that many patients with retro-displacements were symptomless. If a patient were told of the retro-displacement, a vicious circle might be set up. Briefly his practice was: If no symptoms, leave alone; if symptoms were present, he curetted the uterus and replaced it. If the displacement recurred the uterus was replaced and a Hodge pessary inserted for two to three months. If the patient was thereby relieved, nothing further was done, but if her symptoms, &c., returned, then he operated. He had done all types of operation except the absolute fixation and found them all equally successful.

Mr. ROBERT A. HENDRY read the conclusions abstracted from the opening report on the indications for

Surgical Intervention in Retrodeviations of the Uterus Apart from Pregnancy,

presented to the Congress of the Association of French-speaking Gynæcologists and Obstetricians, Geneva, 1923. These were that surgical intervention in uterine deviations, apart from pregnancy, was indicated as follows: (1) In retrodeviations accompanying uterine, ovarian, or parovarian tumours in so far as these tumours did not necessitate the sacrifice of the uterus, the pexy was a complementary operation. (2) In fixed, painful retrodeviations. (3) In fixed retrodeviations accompanied by appendage lesions, unilateral or bilateral, which had resisted medical treatment. If the appendage lesions were such that they required ablation it might be necessary to practise total or subtotal hysterectomy; if such were not the case, the uterine pexy was only a complementary operation. (4) In painful, mobile retrodeviations surgical intervention was only indicated if, when the uterus be replaced, the painful phenomena disappeared. In other cases the pains arose: (*a*) From hysterical and similar states; (*b*) from multiple visceral ptoses. (5) In certain rare cases of obstinate sterility where no other apparent cause could be discovered. (6) In retrodeviations accompanied by repeated abortion where searching examination eliminated the possibility of syphilis. (7) In all cases where, in addition to the retrodeviations, one found a tendency, even if slight, to prolapse with or without perineal lesions. If the perineum were damaged the pexy ought to be preceded by careful vagina-perineal repair. (8) Painless mobile retrodeviations did not require any treatment.

The discussion was then adjourned until the next meeting to be held at Sheffield, on Friday, Nov. 21st.

At the commencement of the meeting Prof. BLAIR BELL described two cases, one of manual perforation of the puerperal uterus, followed by recovery, and the other of thrombo-phlebitis of the right ovarian vein associated with abscesses in the uterine wall.—Mrs. DOBBIN CRAWFORD described a case of primary carcinoma of the vagina.

INFANT HYGIENE, ANCIENT AND MODERN.

Abstract of a Lecture at the Instruction Course for Teachers of Midwives, Midwives' Institute.

DR. H. K. WALLER, lecturing on the above subject in the rooms of the Royal Society of Arts on Oct. 30th, said that one way of approaching it was for enthusiastic welfare workers to enumerate everything modern and call it good, everything ancient as unenlightened and worthless. That clearly would not do. It was difficult for us to picture conditions surrounding infancy in ancient days. Natural selection must have worked surely and ruthlessly in many ways where it was now tempered by more tender social concern. It was certain that throughout all ages there had been no failure in the demand for passionate maternal devotion. The studies of anthropologists showed us that in primitive tribes, where we found the nearest likeness to prehistoric conditions, the task of motherhood was an intricate and exacting profession. So it must always have been, and so it was to-day. For workers in infant welfare there was a stimulus in the fact that of recent years the infant had come in for a wealth of close and scientific study. The speaker traced briefly the history of hospitals, pointing out that hospitals for the wage-earner's wife during the time of childbirth and lying-in antedated by a long while any hospital provision for sick children. One of the oldest children's hospitals in London owed its origin to the revolt of its founder from the rules of the general hospital where he was trained, and where he repeatedly fell foul of the authorities for smuggling children into its wards. Dr. Waller hoped that some surgeon would call attention to the claims of the infant whose mother needed admission to hospital for the treatment of a mammary abscess during the early months of lactation. In many instances breast-nursing could be saved, or re-established after a short interval. But it was still exceedingly difficult to obtain the simultaneous admission of the infant with its mother. The child had to find a hasty shelter, sometimes in most unsuitable quarters, and fell ill, often seriously ill, as the result of a sudden change to unskilled and unsuitable artificial feeding.

It was suggested that we must recognise a certain inherent reluctance on the part of scientists to interest themselves in the habits and needs of the very young child. The human father, like many fathers in the animal world, was somewhat ill-equipped with sympathetic feelings towards his offspring, at least until the awkward inarticulate stage of infancy had been passed. The potential father in the scientist and doctor was, he suggested, not a little responsible for this lack of interest. Dr. Waller went on to say that we could not over-estimate the importance of the craft necessary to be a successful mother or nurse of young children. Good mothers, of which there was happily always a large preponderance, were not often able to impart by means of simple doctrine the essence of their skill. Its acquirement needed beyond all things a patient apprenticeship, and he emphasised the advantage held by women who had themselves to mind children over those who employed others to do it for them. Among the well-to-do the first-born quite often found its mother completely unprepared, devoid of knowledge or practice. In the poor classes the girls were often responsible nurses at the age of 7, and still minding babies when grannies of 70. Neither case was ideal; in the latter the burden was often too heavy. But no one could doubt it frequently produced a degree of skill seldom seen in the former. The lecturer implied no disparagement in mentioning this contrast, but he referred to it because of a somewhat frequent tendency to blame the poor collectively for a lack of skill in upbringing, even a lack of concern for their infants. No infant welfare worker of any experience and powers of observation would subscribe to that view.

Methods of Feeding.

Turning to differences between ancient and modern methods of feeding, the most arresting had been the development of accurate means of artificial feeding. In primitive times lack of success in breast-nursing spelled death for the infant—unless exceptionally it was reared by a foster-mother. Latterly succour by the cow had become so common as scarcely to call for comment. But we were realising the pitfalls in this policy. Despite all the achievements of the chemist, the safety of the successfully breast-fed child was becoming more and more a conviction of physicians. Bottle foods were becoming what they should always have been recognised to be, an invaluable means of saving life in exceptional instances; often a most useful adjunct to, but certainly no general substitute for natural feeding. The superior resistance to illness possessed by the naturally fed baby was too clear to be ignored. Here we were seeing a reversion from modern to ancient customs. The technique of breast-feeding could now be studied and developed in ways that were yielding valuable results. The use of accurate scales is a modern improvement. We had now a means of reducing to measurement what had previously been a matter of guesswork. Nurses and mothers must become proficient in the use of the balances. The speaker held that for the proper understanding of an infant's progress scales which weighed to half an ounce were as necessary as was a clinical thermometer in the supervision of a patient with fever. The objection that the systematic use of scales by a nurse when attending a normal obstetric case would tend to lessen the importance of clinical observation, he considered a poor one. She had at her service an invaluable means of ascertaining that the most important function of the infant was proceeding normally. It was almost her only means of correcting errors of feeding. For the lack of this a great variety of mistakes had crept in and been perpetuated in infant management. In no sense could the means of accurate feeding be said to diminish responsibilities in other directions. As examples of the method details were given of work at an infant clinic. A room was set aside for experimental feeding, and a nurse with special experience placed in charge. To her were referred from the weekly consultations a number of infants, the details of whose progress she recorded. Notes were made of the variation in the yield of the mother's milk at different times of the day, of differences in the yield of the two breasts, of the ease with which the milk was obtained, of the child's behaviour while feeding, of the loss of food sustained by vomiting, and so forth. These notes were returned to the clinic and formed an invaluable aid to the physician when he had to give advice to the mothers.

Referring to dietetic customs at the period of weaning and in the second year of life, Dr. Waller believed there was a danger in imposing on a healthy baby a diet which, from its impressive results in hospital wards when applied to weakly and wasted infants, had crept into the nursery. The essence of this diet was a large preponderance of easily assimilated carbohydrate, and a lavish supply of milk. Here once more it was well worth our while to study the customs of the skilled mothers among the classes where large families prevail. We should find the weanlings' diet far less invalid in type; often indeed it appeared startlingly robust in character. Milk tended to drop out quite early, and the common food of the adult to replace it. Were it not so often spoiled by an undue indulgence in sweets and chocolates, this diet appeared to suit the normal infant well. After commending the excellent modern type of loose-fitting wool clothing which was replacing the cumbrous wrappings of olden days, the importance of safeguarding the infant from catarrhal infections was mentioned. An example was given of an affectionate relative with a pneumococcal abscess in her antrum infecting a new-born child, with all but fatal results. The prevalence of infective catarrh of the nasal passages is one of the grave dangers to which babies are subject. The opinion was expressed that many cases of conjunctivitis in the new-born were secondary to nasal infection, and that their prevention and cure was advanced by suitable disinfection of the infant's nose.

An important aspect of infant management had developed from the recent advances made in our understanding of the baby's psychology and its nervous disorders. The writings of Cameron on this subject contained brilliant and fascinating suggestions and had shown the importance of arranging a calm and suitable environment for the child.

In conclusion Dr. Waller referred to the accusation sometimes made that much in our modern ways of infant supervision received the contempt of the older school. The veterans who boasted that in their hardier and wiser generation they had no need of these things might act as a useful check on methods that were iconoclastic. But were the veterans infallible? Were past generations always so successful? He quoted a memorial in a village church. It seemed to have been designed to commemorate impressively the death of "William, the first-born child of Sir Wm. . . . Bart, who died, poore chylde, Oct. 16th, 1672, aged 11 months." The inscription was cut large in the centre of the marble slab. But beneath it, and above it, and around it in smaller and smaller type as the space diminished, had been added the doleful record of William's brothers and sisters. Richard, John, Henry, Emma, Jocelyn, Mary, and a second William all followed in hapless succession; the 3rd, 4th, 5th, 7th, 8th, 9th and 11th children, their ages ranging from a few weeks to 14 months. There may have been later survivors. But of the first 11, 8 had perished in infancy: a mortality of 72 per cent. The baronet's lady might have profited and the tablet been less crowded had she been able to attend an infant welfare centre such as the twentieth century had seen arise.

Reviews and Notices of Books.

PROCTOLOGY.

Diseases of the Rectum, Anus, and Colon. By SAMUEL GOODWIN GANT, M.D., LL.D., Professor and Chief of Department for Diseases of the Colon, &c., Broad-street Hospital, New York City. London and Philadelphia: W. B. Saunders Company, Ltd. In three volumes. Pp. 543, 545, and 528. £6 6*s*. the set.

Dr. Gant's exhaustive treatise in three volumes on rectal and colonic ailments is before us, but the author himself has passed away, leaving this record of a great achievement. The reader cannot fail to grasp Dr. Gant's technical methods for there are 1138 illustrations to the text, many of them semi-diagrammatic and all of them clear. The chapters dealing with abscess and fistula are well and profusely illustrated, and the author's experience of the latter is evidently exceptional, for he has operated on 5000 patients, which corresponds roughly to the number of cases dealt with at St. Mark's Hospital for Fistula over a period of about 30 years. The division operation is preferred to the excision method and both methods are well discussed; the author, contrary to the accepted view, considers that better results can be obtained by not confining patients to bed after operation.

Dr. Gant prefers the operation of ligature for hæmorrhoids which he conducts under local anæsthesia, and confines his patients to bed for only three or four days. Prior to the use of local anæsthesia he gave preference to the clamp and cautery operation. He believes that when recurrence occurs it follows ligature, clamp, and cautery, and the Whitehead operation with equal frequency, but also states that a permanent cure nearly always follows all three operations. With regard to injection treatment he holds that it is not uniformly curative, nor does it always temporarily arrest bleeding or protrusion, and that it is best suited for moderate-sized bleeding and protruding piles and should never be employed when hæmorrhoids are large, inflamed or ulcerated; he states that "when the injections go wrong the patients suffer a great deal more than if they had undergone the radical treatment."

A high percentage of cures is claimed in operations for cancer of the rectum. In discussing the operative technique of carcinoma of the rectum the author describes a perineal operation in which he brings down the upper end as an anus after removal of the sphincters, and other methods from below in which he retains the sphincters with or without removal of a portion of the sacrum. Those who practise excision from below in this country are for the most part agreed that it is desirable to perform a preliminary colostomy, to remove the rectum entire with its sphincters, and to close the upper cut end, aiming at a thorough removal and a clean wound. When operating through the abdomen the author prefers the abdomino-anal method to the abdomino-perineal, though he resorts to preliminary colostomy in obstructive cases. Few, if any, surgeons in this country now practise the abdomino-anal method in preference to the abdomino-perineal. With the statement that "an artificial anus is unnecessary in the treatment of colonic and sigmoidal cancer unless growth is inoperable" we cannot agree. Diverticulitis, constipation, obstipation, intestinal stasis, and coprostasis occupy a large portion of the third volume; some remarkable operations for their relief are described, as, for example, the method of colopexy on p. 258, and little or no information is given as to their results.

We consider that the book would be improved in a future edition if less heavily weighted with material that has but a remote bearing on the subject—e.g., an account of spina bifida. The chapter on examination of the intestinal tract, again, deals with test-meals, the odour of fæces, the pathology of the urine and blood, and even includes an illustration of a diaphragmatic hernia. The following passage occurs: "Recto-colonic tubercular ulcers and tumours are often mistaken for bacillary, luetic, amœbic, and balantidic colitis, inflammatory growths or gummata, and to clear up the diagnosis in doubtful cases patients may be submitted to a tuberculin test." The author is convinced that splitting the anal canal "including division of the sphincters, fibres of the levator ani muscle . . . . by a bold stroke with the author's razor blade bistoury well up into the rectum," is the best operation for fissure, and by this method he has cured over 1000 cases. Rectal surgeons in this country would shrink from this heroic procedure. Indeed, throughout the book we find ourselves in frequent conflict with the author's pathological views and methods of treatment. But it is of great interest to learn the views of our distinguished colleagues in America, and we recommend a study of the book to proctologists in this country as a stimulating exercise.

A Treatise on the Diseases and Injuries of the Rectum, Anus, and Pelvic Colon. By J. RAWSON PENNINGTON, M.D., F.A.C.S., Proctologist to Columbus Hospital, Veteran's Hospital No. 30, and U.S. Marine Hospital. Philadelphia: P. Blakiston's Son and Co. 1923. With two plates and 677 illustrations. Pp. 933.

THE author dedicates this volume to the memory of some of his early teachers, Herbert Allingham, Alfred Cooper, David Goodsall, Charles Boyd Kelsey, and the volume contains portraits of many distinguished surgeons. Some idea of the scope of this work may be gathered from the fact that 46 pages and a like number of illustrations are devoted to the anatomy of the rectum, which is described in an attractive manner. Imperforate anus is well discussed, and it is interesting to note that in a summary of 223 cases operated on by various methods and collected from various sources only 16 reached adolescence and but 13 passed the adult age; it must be presumed that most of these were afflicted with either a colostomy or an incontinent anus. Gunshot wounds of the rectum are considered in the light of experience gained in the late war; this chapter might be improved in a future edition if gunshot wounds involving the rectum were considered under two headings: (1) those which penetrate the peritoneal cavity, (2) those associated with buttock wounds without involvement of the peritoneal cavity. We agree with the author when he advocates "excision" of fistula in ano, but it should be made clear that the method is only suitable for a limited number of cases; treatment by the ancient method of "string constriction" should not, we think, be encouraged. Mr. Pennington has come to the conclusion that the best operation for hæmorrhoids is the "open" method, which, he states, "consists in excising sufficient of the covering of the varicosities, so when the pathologic condition is removed the operated field will resume its normal state and relation to the contiguous parts." It is not clear from the text that the "open" method is an improvement on the present-day method of ligature and excision. We do not agree that "there is considerable risk of secondary hæmorrhage" after clamp and cautery. It is satisfactory to see that adenomyomata involving the rectum are referred to. These tumours have in the past, no doubt, often been mistaken for carcinomata, and it is important that they should be recognised, because they can be cured, in the early stages at any rate, by radium, and a severe operation is thus avoided. In discussing the operative technique of carcinoma the author describes various methods of excision without committing himself to a definite preference. The abdomino-perineal method is described but not the modern perineal excision after preliminary colostomy by the method used at St. Mark's Hospital, which now has so many adherents in this country. Diseases of the pelvic colon are considered separately at the end of the volume and are well discussed, especially megacolon and diverticulitis. A complete bibliography is attached to each chapter, the value of which is increased by an index of the names of the authors referred to (about 1300) with page references.

In the interesting historical introduction the royal bistoury used to operate on Louis XIV., in 1687, is depicted. The fees for the surgeon and his assistants on this occasion were truly royal, amounting to $73,000.

As a work of reference this book will prove of great value to proctologists, and as a text-book for the practitioner it should be more than sufficient. It is well printed and profusely illustrated.

OPERATIVE DENTAL SURGERY.

Second edition. By J. B. PARFITT, L.R.C.P., M.R.C.S., L.D.S., Dental Surgeon and late Lecturer on Operative Dental Surgery to the Dental School of Guy's Hospital. London: Edward Arnold. With illustrations. Pp. 342. 21*s*.

MUCH has been written on the subject of operative dentistry, but we do not know of any other book which bears so authentic a touch as this. It is practical in the sense that every page is evidently derived from personal experience. There is no section dragged in for the sake of completeness and obviously written up for the occasion. The chief changes in this edition are to be found in the chapters on cavity preparation and pain saving. The section on cavity preparation is extremely good, and covers the ground very completely. The chapter on pain saving contains some useful matter, but also reveals the gap in dental technique. Painless dentistry is not yet a possibility, in spite of various much-lauded methods. Mr. Parfitt advocates the use of local anæsthesia for abolishing sensation in conservative dentistry. Often it succeeds, yet there are cases in which it is unavailing. In some cases a satisfactory anæsthesia may be produced in this way, but an obstinate tenderness of the tooth may follow, which rather discounts the patient's gratitude for a painless operation. Mr. Parfitt rightly lays stress on the evil of using too much adrenalin. There can be no doubt that many of the toxic symptoms which occasionally follow the use of novocaine are really due to the adrenalin incorporated in the tablets. Perhaps the most suggestive chapter in the book is that on "Infection and Cleanliness." It is quite short, but every word tells. So much craftmanship enters into dental operations that there is a tendency to view dentistry from that standpoint and to overlook the fact that operative procedures may open up many loopholes for infection of the dental tissues. The rigid standards of cleanliness essential in surgery are not practicable in dentistry, and some compromise is necessary. The technique which Mr. Parfitt has elaborated in this book represents a practical possibility open to every dentist practising under average conditions. It may not be absolutely watertight, but there can be no doubt that its adoption would eliminate many cases of dental infection which have supervened upon operative measures upon the teeth.

Far Eastern Association of Tropical Medicine.

Transactions of the Fifth Biennial Congress, held at Singapore, 1923. By A. L. Hoops, M.D., and J. W. Scharff, M.B. London: John Bale, Sons and Danielsson, Ltd. 1924. Pp. 974. 40*s.*

Some idea of the activities of tropical workers in the Far East may be obtained from a perusal of an informative and imposing volume edited by Dr. A. L. Hoops, P.M.O., Straits Settlements, and his able assistant, Dr. J. W. Scharff, who also acted as the hon. secretary of the congress. The book is handsomely got up, and contains information which must have required a considerable amount of energy to collect and still greater patience to edit, as it comprises some 78 papers. The writers of these papers, which were read at the congress, hailed from China, Japan, Formosa, the Dutch East Indies, French Indo-China, the Philippines, Borneo, as well as from India, Hong-Kong, Shanghai, the Malay States, and Straits Settlements. The cosmopolitan character of the congress well bears out the theme of the introductory address of welcome by the Governor of the Straits Settlements, that in the theatre and laboratory "there is neither East nor West, border nor breed nor birth." In his presidential address on the prevention of disease in the tropics Dr. Hoops referred to the activities of previous congresses and the benefits which had accrued therefrom. A gap of eight years in the meetings had resulted from the late war.

The opening address on malaria, by Sir Malcolm Watson, is followed by a number of papers by Wellington, of Negri Sembilan; by S. C. Howard and V. A. Stookes, on malaria control on rubber estates in Malaya and in Sarawak respectively; E. W. Walch writes upon malarial epidemics caused by *Anopheles sinensis;* W. B. Doovenbros, on sanitation on rubber estates in Sumatra. M. Koidzumi describes the anophelines of Formosa. S. R. Christophers, the well-known authority on malaria, has a thoughtful article on measurement of the enlarged spleen, and Yas Kuno, of Mukden, discusses the same subject. A paper of special merit on the treatment of dementia paralytica by malaria is by F. H. Van Loon and Dr. L. Kirschner, of Batavia. From this it appears that the disease is relatively uncommon, and that native patients usually are absolutely immune to benign tertian malaria. The aspect of malaria to mental disease and tropical neuroses (amok and latah) peculiar to Malaya, the latter by R. D. Fitzgerald and Sir D. J. Galloway, deserve especial mention. A. T. Stanton discusses measures for control of beri-beri in the Far East. Dr. Wu Lien-Teh has much to tell of plague in wild rodents and the tarabagan—a fine record of original work.

There are numerous contributions on dysentery, the pseudo-typhus of Sumatra, the treatment of leprosy, spirochætosis icterohæmorrhagica, examination of the liver by X rays, &c. Enough has been said to demonstrate the value of the work accomplished. Every practitioner in the tropics would do well to keep it on his shelf.

The Transpiration Stream.

By Henry H. Dixon, D.Sc., F.R.S., Professor of Botany in the University of Dublin. London: University of London Press, Ltd. 1924. Pp. 80. 2*s.* 6*d.*

This little book contains a reprint of three lectures on the transpiration stream delivered, at the invitation of the Senate, before the University of London; in it the author summarises the present position of the cohesion theory of the ascent of sap. To those readers who are unfamiliar with his earlier publications on this subject the present account will hardly be sufficiently explicit, but the advanced reader will find here reference to recent work on the subject, together with Prof. Dixon's views on the significance and interpretation of this work.

Ear, Nose, and Throat Nursing.

By J. Hardie Neil, M.B. (N.Z.), M.R.C.S. Eng., Ear, Nose, and Throat Surgeon, Auckland Hospital, New Zealand. London: H. K. Lewis; Auckland: Clark and Matteson. Pp. 31.

Mr. Hardie Neil has written these practical notes for the benefit of senior nurses, and as a guide to the general routine of the department which may, in parts, be of assistance to resident medical officers. The book is divided into sections on the ear, nose, pharynx, œsophagus, and larynx, each of which begins with a short description of the anatomy, and continues with an account of examination methods, of the common forms of disease, and of the more important operations. Nurses are told what complications to expect, what to do in cases of emergency, and what instruments to prepare for operation. There are some useful anatomical drawings and good illustrations of the patient's position for examination and operation. Apart from a few small slips, the little book is well and carefully written, and should be very useful within its size and scope.

The Care of the Baby.

Seventh edition. By J. P. Crozer Griffith, M.D., Professor of Pædiatrics in the University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 478. 12*s.* 6*d.*

This book, described as a manual for mothers and nurses, contains a number of practical directions for the management of infants and children in health and in disease. It has naturally undergone a considerable amount of revision since its first publication in 1895, and the present edition, the seventh, has been brought well abreast of the teaching of to-day. Among the formidable array of volumes written for the guidance of mothers, Prof. Crozer Griffith's book takes an honourable place and well deserves its sustained popularity. It is very much more readable than are most books covering the wide range of topics connected with the care of infants and children, partly, no doubt, because it is not broken up into short sections. The hygiene of pregnancy is discussed in the first chapter of the book, succeeding chapters being devoted to details of the infant's growth, toilet, clothes, food, sleep, exercise, and training. The last section of the book, consisting of 150 pages, is devoted to the sick baby; this section, which is particularly well done, has been written especially for those mothers who are unable to obtain medical aid in an emergency. An appendix has been provided containing various recipes for food and medicine, as well as directions for the preparation of different kinds of baths, poultices, disinfectants, and so on. These are given in sufficient detail to enable any intelligent woman to follow them with ease. In a few instances the author's teaching is at variance with that of most pædiatrists in this country, such as the statement that during the first three months of life seven to ten feedings should be given in the 24 hours, including one or two night-feeds; or the advice that a meal should be given between 9 and 10 P.M. to a child of 12 to 18 months. These are small blemishes, and the book may safely be recommended to all who have the care of infants.

What Every Mother Should Know. Second edition. By CHARLES GILMORE KERLEY, M.D. New York: Paul B. Hoebner. Pp. 103. $0.50.

THIS little book is designed by its author to serve as a ready reference for busy mothers with regard to the care of their children, its purpose being "to place in the hands of the mother of moderate means concise, readily understood, and practical instruction." The teaching given in the 13 chapters of the book is simple and elementary, and most of the questions are dealt with on which a mother is likely to need instruction. The only points on which English physicians would be likely to differ from the author are the advocacy of a night-feeding during the first three months of life, and the undue importance given to constipation—i.e., infrequent stools—in a breast-fed baby. Where a breast-fed infant is steadily gaining weight and the motions passed are normal in colour and consistence, the actual number of stools passed in the 24 hours really matters little. A useful feature of the book is the interleaving with blank pages for notes.

AN OUTLINE OF MEDICAL TREATMENT.

Grundriss der Klinischen Therapie Innerer Krankheiten. Zweite Auflage. Von. Prof. Dr. GEORG KLEMPERER, Direktor der IV. medizinischen Universitatsklinik; arztl. Director des Städt. Krankenhauses Moabit in Berlin. Unter Mitwirkung von Oberarzt Dr. L. DUNNER. Berlin: Urban and Schwarzenberg. 1924. Pp. 268. Sch. fr.6.25.

THAT a second edition of this book has already been published is a tribute to its popularity in its country of origin. It is a short treatise on clinical therapeutics and is doubtless of value to the busy German practitioner. To the English reader its only appeal can be as an index of accepted common methods in a foreign country. An appendix gives a list of useful German prescriptions.

JOURNALS.

BIOCHEMICAL JOURNAL. Vol. XVIII., No. 5.—The first paper, by H. W. Southgate, on the Dietetic Value of Barley, Malt, and Malted Liquors as determined by their Vitamine Content, will prove of interest to those engaged in liquor controversies, since it is shown that, although barley and malt contain large quantities of water-soluble B, beer possesses very little of this vitamin.—The mechanism by which a dead fœtus is removed in utero has been studied by C. N. H. Long and A. S. Parkes. In their paper, entitled On the Nature of Fœtal Re-Absorption experiments, are described from which it would appear that the fœtus is dissolved by its own autolytic enzymes, and that the process is not one of putrefaction, nor are the enzymes derived from the uterus.—A series of papers deal with methods. These include: A Colorimetric Method for the Direct Estimation of Ammonia in Urine, by A. P. Orr. The method depends on the colour produced between ammonia and phenol in the presence of sodium hypochlorite.—Estimation of Sugar in the Blood, by E. G. B. Calvert. The author replies to criticisms on his original modification of the Folin-Wu method, and describes further alterations which obviate the necessity of a torsion balance.—A Method for the Estimation of Iron in Small Quantities in Biological Substances, by M. M. Murray. The iron is estimated, after ashing, by means of $N/80$ $KMnO_4$. The introduction of a reductor, composed of cadmiumised zinc, is the original part of the method.—Note on the Estimation of Uric Acid by the Hopkins-Folin Method, by R. C. Garry. The author describes an ingenious method of performing a "blank" control, and other methods designed to overcome the difficulty of appreciating the end-point.—Method of Estimating Minute Amounts of Iodine in Biological Material, by F. C. Kelly and A. D. Husband. This paper contains a brief review of the methods in use at present, together with the description of a modified technique.—A Colorimetric Method for the Estimation of Sugar in Blood, by F. J. Paton. The author suggests that the colour given by glucose and 3–5 dinitrosalicylic acid as the basis for the new technique.—A Critical Study of the Methods of Estimating Cholesterol and its Esters in Tissues, Part II., by J. A. Gardner and F. W. Fox. This paper deals with possible fallacies and the mode of extraction of cholesterol from the tissues.—Perhaps one of the most interesting communications is that by P. T. Herring, J. C. Irvine, and J. J. R. Macleod, called the Efficiency of Various Sugars and their Derivatives in Relieving the Symptoms caused by Insulin in Mice. The experimental work on the animals was performed by Prof. Herring, whilst the sugars employed were made and purified by Prof. Irvine. The results are commented upon by Prof. Macleod. There can be no doubt that this is one of the most exact pieces of chemical research performed on the subject. The general conclusions arrived at were that only those sugars easily fermented by yeast are most efficient in the treatment of convulsions—i.e., glucose and mannose. Fructose is nothing like so efficient, and acts in a temporary manner. Galactose is even worse than fructose. Maltose is slow in action, whilst lactose is without action. Various other substitution compounds were also tried.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

XXII.—"LOCK-UP" SURGERIES.

BY HAROLD S. BEADLES, M.R.C.S. ENG.,
CHAIRMAN OF INSURANCE COMMITTEE AND SECRETARY OF PANEL COMMITTEE, WEST HAM.

THE system of medical attendance and treatment under the National Health Insurance Acts has of recent years brought prominently before public notice the question of the provision of what are generally known as "lock-up" surgeries. Of course, the use by medical practitioners of these "lock-up" or "branch" surgeries prevailed long before the Insurance Acts were thought of. They owed their origin primarily to the recognition by practitioners of the desirability of providing facilities whereby their personal services could, at specific times in the day or at call, be brought nearer to the homes of their patients.

Rural Needs.

In the case of sparsely populated and extensive rural areas, where the inhabitants live in villages and isolated hamlets, there is no doubt whatever that the existence of a lock-up or branch surgery has been, and is still, a necessity, and can be said to furnish the only satisfactory arrangement. Resident medical practitioners must necessarily be few and far between in such areas; and those who use the surgeries have to spend much time in travel from their homes to their patients. They must, of course, reside as near as possible to the centre of their practices so as to render themselves more readily available day and night to the greater number of their patients. Consequently some form of non-residential provision for the more distant areas of these practices becomes essential. This applies with equal force to the private and insurance sides of general medical practice.

With the present-day extension of the telephone service, communication between such surgeries and the doctors' private houses has become much easier. Delay in establishing communication with a practitioner in emergency must inevitably result in danger to the patient and dissatisfaction to the doctor himself. A practitioner having voluntarily established a lock-up or branch surgery imposes upon himself, therefore, the moral obligation to provide adequate attendance and treatment thereat and therefrom. While it is conceivable that the establishment of a lock-up or branch surgery in or near an outlying village would reduce unduly the extent of the practice available to a doctor resident in that village, with the consequent risk of making it impossible for the resident practitioner to derive an adequate living from the remaining portion of the population, nevertheless action for the prohibition of such an establishment should not be lightly undertaken, because it might tend to restrict in some degree free choice of practitioner by patients, and also to militate against the best interests of the medical service of the area generally.

This phase of the subject is recognised in National Health Insurance practice, as is evident from the following reference thereto in the mileage schemes adopted by some insurance committees:—

> "Provided that, in cases where the practitioner (or any partner of his) has a surgery which is nearer to another practitioner's residence than it is to his own, the credit (i.e., for mileage grant) shall be based on the distance from that surgery to the residence of the insured person."

In other words, this means that if practitioners in rural areas open lock-up or branch surgeries in outlying districts where other practitioners reside, they cannot always expect to receive credits for mileage measured from their own residences to the homes of patients residing within the vicinity of such surgeries.

Urban Needs.

In the case of more thickly populated urban areas and towns the need for the lock-up surgery system is not so apparent, at least from the point of view of the public. Generally speaking, the residences of practitioners in such areas are so placed as to be within a mile or so of their farthest patients and the number of practitioners resident within a small area is much greater. The incentive to establish a lock-up surgery in such an area cannot therefore be regarded on the same plane as in the case of rural practice. Here the convenience of the patients does not appear to be the primary consideration. Extension of practice, the desire for improved residential environment, the dearth of residential accommodation in building up a new practice—these would appear to be the governing factors.

Now while the desire to extend a practice is quite legitimate in its way, it should not be permitted to dominate the best interests of the patients needing advice and treatment and of the other practitioners resident in the district. But the wish for improved residential surroundings, especially in a number of areas of this country, is perfectly comprehensible. The extraordinary thing is that some of the urban areas should enjoy a resident practitioner at all. Persons with the nurture and training of a physician need considerable courage in addition to their other gifts in order to spend the best years of their lives in the squalid surroundings presented by some of these districts. The prospect for the wife and family of such a practitioner is far from alluring. The charge has been levied that, the Insurance Acts having provided a well-assured income in respect of the treatment of the poorer classes, practitioners and their families have migrated to more salubrious surroundings during their hours of rest and recreation. If there were any truth in this charge the difficulty has been well met by the action of the responsible authorities under powers conferred by the provisions dealing with surgery accommodation in the Medical Benefit Regulations. Yet granting the conditions of some of our town areas practitioners can hardly be blamed for taking the earliest opportunity of improving their lot in respect of living accommodation and environment.

Drawbacks and Safeguards.

The establishment of a lock-up surgery by a medical man or woman commencing practice in an urban or town district is, however, least worthy of approval at the present time, notwithstanding the prevailing shortage of housing accommodation, and should not be recognised for insurance purposes unless the practitioner lives within easy distance of the surgery provided, and unless his services at and from the surgery are as readily available at all times as they would be if it were situated at his place of permanent residence.

Whatever the motive for the inauguration of a lock-up surgery may be, and whether it be intended for the use of private patients or insured persons, such an establishment cannot serve the best interests of either the medical profession or of the sick public unless adequate facilities are provided thereat for calls upon the practitioner's service at any time of the day or night by the employment of a caretaker and the provision of a telephone. Efficient safeguards must also be effected against the possibility of the other practitioners resident in the district being burdened unduly with the absent practitioner's responsibilities.

Some of the less friendly critics of the State insurance medical service have, from time to time, pointed to lock-up surgeries as evidence of the alleged unsatisfactory provision made for the medical needs of the insured members of the community. In a few cases such criticism may be justified in relation to a very small number of insured persons, but no sweeping indictment of the service on this account can be substantiated. It may truthfully be said that the establishment of the service has rendered obligatory upon all the contracting practitioners the provision of many of the good features which existed in well-conducted private practices in pre-insurance days. With the passage of time the administrators of the Act have had opportunities for comparison, from which has resulted the endeavour gradually to raise by legislation the standard in every direction, including surgery accommodation.

In the last issue of the terms and conditions of insurance medical service it is laid down that a practitioner is required to provide proper and sufficient surgery and waiting-room accommodation for his patients, having regard to the circumstances of his practice. The form of words used here is very wide in its application and embraces the obligation to provide, if necessary, a lock-up or branch surgery, equally with the abandonment of such a surgery if, in the opinion of the authorities, circumstances demand it. It is known that some practitioners own branch surgeries which they work wholly through permanent assistants. Rarely, if ever, do they put in an appearance or answer calls from patients accustomed to use such surgeries in the belief that their treatment is under the supervision of the principals whose names appear on the door-plates. These may be characterised as among the worst forms of lock-up surgeries and might well, in certain conditions, give rise to the suggestion of practising under misrepresentation.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 8, 1924.

DOCTRINAIRISM IN MEDICINE.

The trial of Rex *v.* Hadwen has been one of profound interest to the public and to the medical profession, but its significance can only be really understood if the issues are made clear. There are temptations to regard the case as an attempt to persecute, in accordance with an extreme doctrinairism, a qualified practitioner for holding unorthodox opinions; it really was an inquiry into certain circumstances in the clinical conduct of a case, to decide whether there had been negligence, and, if so, whether that negligence amounted to manslaughter. At the Gloucester Assizes Dr. W. R. Hadwen was acquitted by a jury on a charge of manslaughter arising out of the death of a patient. Such a charge is rarely brought against a medical practitioner, and it is for every man and woman to consider the circumstances under which such a charge was brought and what is the sequence of events when such a charge is heard. To enable them to do so a verbatim report of the evidence and of Mr. Justice Lush's summing-up is given in a Special Supplement to this issue of The Lancet. Dr. Hadwen was acquitted of manslaughter. It is necessary to look closely at the implications of his acquittal.

Dr. Hadwen was acquitted because, holding the views that he did, his conduct did not amount to wicked negligence. It was not enough for the prosecution even to prove that, had the doctor been careful, the patient would have had a chance of survival. The jury were directed that only if negligence were of so gross a character as to make it wicked negligence would it amount to manslaughter. The verdict did not decide whether the child did or did not die of diphtheria. The jury were not asked to formulate a conclusion as to this, which is only one of the many points on which medical men will like to form their own conclusions after a careful study of the whole of the evidence. The jury were not asked to say whether Dr. Hadwen's views on the treatment of diphtheria were those of a wise medical man or not. "You are not here," said Mr. Justice Lush to the jury, "as a tribunal to criticise his views." It will be seen that the prosecution set themselves a difficult task in endeavouring to secure Dr. Hadwen's conviction upon an indictment for manslaughter, however undesirable the treatment of his patient might appear to other members of his profession. The jury were, in fact, not asked to comment on the scientific issues which were at stake or to assess the danger to society of a medical man who holds the views revealed at the trial, in the light of scientific knowledge as it stands to-day.

We are still at liberty to do both these things. Belief in the value of diphtheria antitoxin is universal among bacteriologists and to the medical profession as a whole the evidence is conclusive that antitoxin saves life in cases of diphtheria in direct proportion to the earliness at which it is administered. Medical officers in charge of fever hospitals hold that antitoxin administered early would have saved the lives of a large proportion of diphtheritic cases admitted moribund to these hospitals. Dr. Hadwen thinks otherwise. He is bound by views expressed in public that diphtheria comes and goes quite independently of antitoxin and that the only change which antitoxin can produce in any case is for the worse. In 1917, writing of the Registrar-General's statistics, he remarked that in spite of the rigorous antitoxin inoculation for the last twenty years, the "bacteriological necromancers" had failed to bring down the death-rate to what it was twenty years before the date in question. We are not here concerned with Dr. Hadwen's use of figures, but only with the opinion he holds on the value of antitoxin. Opinion in regard to methods of treatment founded on theories of bacterial causation is, doubtless, not uniform throughout the medical profession. In therapeutics, as in politics, there is an extreme Right which clings to time-hallowed views and an extreme Left which may be provocatively in advance of ordinary practice. Both extremes lay themselves open to charges of malpraxis; the Right, in that they have not applied to a sick person the knowledge which medical science claims to have at its disposal; the Left, in that they are interfering with the liberty of the subject by employing protective methods not universally regarded as advisable. It will be recognised that the doctor is susceptible in ordinary degree to human frailty and human prejudice, and no one demands of an elderly practitioner the same degree of physical activity or mental alertness that is shown by his junior—wants which may be compensated by maturer judgment and better knowledge of the world. But where a medical practitioner's view in a vital question comes into conflict with that of the vast majority of his professional brethren, he has the alternatives of sinking his own judgment or of having his conduct reviewed in open court.

◆

THE PROPHYLAXIS OF DIPHTHERIA.

All who are interested in the question of the prophylaxis of diphtheria and its application on a large scale in this country will find much useful information on the subject in the admirable report to the League of Nations by Dr. Louis Van Boeckel,[1] the Director of the Laboratory of the Belgian Health Department. After an exhaustive summary of the history, technique, significance, and practical applications of the Schick test, the author comes to the conclusion that "it is a sure and practical method of determining susceptibility to diphtheria." Admitting that the use of the toxin-antitoxin mixtures may not form the ideal method of protection, and that possibly in the future they may be supplanted by some other kind of anti-diphtherial vaccine, he considers they confer an immunity lasting for at least seven years, and in all probability for life. Of the general safety of the method there appears to be no doubt, but the report rightly emphasises the necessity of some form of State control for the standardisation of the toxin used for the test and of the mixtures employed for immunisation. The Regulations of the U.S. Public Health Service are "designed not only to compel the manufacturers to supply a product which fulfils all the desired conditions, but also to prevent any risk of infection or accidental intoxication." It was inevitable that the report should be based mainly on the remarkable work of Dr. W. H. Park and Dr. A. Zingher in New York. It is surely no mere coincidence that the city in which immunisation has been most thoroughly and systematically carried out should of all the great American cities show the most striking and steady fall in its diphtheria mortality-rate. To quote an American medical contemporary[2]: "The figures now available are a challenge to every city in the United States" (and, may we add, in Great Britain), "which has a diphtheria mortality-rate higher than the strikingly low rate of New York City."

---

[1] The Prophylaxis of Diphtheria. League of Nations. C. 169. M. 45. 1924. III.

The success in New York has been synchronous with an intensive and unremitting campaign carried on for seven years and resulting in the testing and immunisation of hundreds of thousands of children. Beside this great achievement the results obtained in Edinburgh by Dr. W. Robertson and Dr. W. T. Benson, and reported on another page of our present issue, may seem very insignificant, but, so far as we are aware, they represent the first serious attempt in this country to protect all the school-children of a large city against diphtheria. As was only to be expected, many difficulties were encountered, but they have for the most part been surmounted satisfactorily. It is most gratifying to learn that it was possible to obtain parental consent for the testing and protection of 43·3 per cent. of the children, and that in the case of a later visit to a particular school consent was given to immunise 50 per cent. of the remainder. Such an experience goes far to prove that the parents were satisfied that the children inoculated on the first occasion had not suffered in any way from the process. There is little reason, indeed, to believe that severe reactions or inflamed arms are common in children of school age, and the fact that in the better-class fee-paying schools absenteeism as the result of inoculation was as low as from 2 to 3 per cent. suggests that the higher percentage in the lower class schools was not really necessary. Dr. Benson, as regards his methods of propaganda, his certificates of immunity, and his insistence on the necessity of enlisting the sympathy and assistance of the teaching staff of the schools concerned, has followed closely the methods of Dr. Zingher, and we can only hope that his efforts will be rewarded with equally striking results. Some time must necessarily elapse before a definite opinion can be given regarding the success of such a scheme, as the acquiring of active immunity is, at best, a slow process. The Edinburgh results, however, so far as they go, seem very encouraging, and of one group of susceptible children no fewer than 91·3 per cent. were found to be immune within six months of inoculation. The important fact in the meantime, however, is that Drs. Robertson and Benson have clearly demonstrated that, in spite of the opposition of the prejudiced and ignorant, a large proportion of parents in this country will be found not only willing but eager to permit the application of this method of protection for their children, and that the difficulties inseparable from such a considerable undertaking can be overcome by judicious propaganda, by the tact and enthusiasm of those in charge of the work, and by the intelligent coöperation of the school authorities.

◆

HEALTH AT SEA.

Seafaring has always been one of the staple industries of the British race, and after the initial discomforts are surmounted the life is held to be a healthy one. How far this impression is justified by facts cannot be stated with certainty. The Ministry of Health, which keeps a watchful eye on the bodily welfare of the citizen plying his trade above or below dry land and on the inland waterways, has little time to spare for those whose business is on the high seas. The removal a year ago of the seaman's disability in regard to treatment for venereal disease was due to private enterprise, although the Ministry was sympathetic. The Navy has a well-organised medical staff to record and analyse the incidence of disease and death on vessels of war, but mortality and morbidity in the Mercantile Marine are little more than items among the varied returns of damaged goods and broken ships compiled by the Board of Trade. While the Board of Trade is concerned with the widest aspect of welfare at sea and has under constant consideration the conditions under which the merchant seaman lives, it apparently attaches little importance as to how he dies. Yet the collection of accurate vital statistics and their proper interpretation is one of the first essentials towards establishing satisfactory living conditions. For the Mercantile Marine such returns are not available, and it is in this connexion that Fleet Surgeon W. E. Home criticises elsewhere in our columns the supervision of health at sea exercised by the Board of Trade. He complains that no figures are given from which the death-rates might be calculated with even approximate accuracy, and further that the listed causes of death bear evidence of lay origin. These criticisms may be just, but to remedy the shortcomings is no simple matter. In the first place, as Dr. Home himself points out, the total number of men serving in the Mercantile Marine can be calculated only very roughly on the basis of the numbers forming the first crews of vessels during the year, and very few of those who follow the sea spend an entire year on a ship. Greater accuracy might result by taking the total number of "crew-days" run in the Mercantile Marine in one year, and then dividing the number by 365. This would give the number of hypothetical years passed in the service by crews, and from these the annual rate of mortality could be determined. In the second place, the difficulty in calculating the disease and mortality-rates among seamen lies in the fact that only about 1000 ships among the 8000 on the British Register are required by law to carry a qualified surgeon. Thus, while on the lines indicated the total mortality might be calculated with a degree of accuracy, the question of cause of death will depend on the diagnoses of the masters of the ships in the greater proportion of cases. The ship's captain may possess an excellent working knowledge of the medicine-chest, but his diagnosis is not likely to be of value from a statistical point of view. In this connexion it would seem advisable that the Board of Trade should differentiate between the reports submitted from ships which carry a surgeon and ships where medical questions are decided by a layman. While Dr. Home's figures indicate that the mortality among merchant seamen is higher than that in the Navy or in the Army, it must be pointed out that, compared with the mortality per 1000 of males in England and Wales between the ages of 20 and 55, it is low. For the Mercantile Marine the rate is 2·08 per 1000; for the latter it is 7·9 per 1000. Nearly all those who sail the seas are medically examined before a voyage, and there is no question that the provision of more accurate and fuller statistics would be of the greatest value as a basis for improving the health of the merchant service. We ought to know, for example, the effect of the different routes traversed by ships. Some of these are reputed healthy, such as the North and South Atlantic routes, and some unhealthy, as the Suez route, and the West and East African coastal routes. The Board of Trade might enlist the coöperation of the Ministry of Health.

---

GENERAL MEDICAL COUNCIL ELECTION.

NOMINATIONS of Direct Representatives of the medical profession to the General Medical Council were in the hands of the respective registrars on Thursday last, when the list was closed. As far as is known at the time we go to press the candidates are as follow :—For England and Wales : R. A. Bolam, Newcastle-on-Tyne ; H. B. Brackenbury, London ; J. Brown, Blackpool ; H. J. Cardale, London ; H. F. Devis, Downend, near Bristol ; R. Fielding-Ould, London ; E. A. Gregg, London ; J. A. Macdonald, Taunton ; Sir T. J. Verrall, Bath ; F. H. Westmacott, Manchester ; for Scotland, Sir Norman Walker, Edinburgh ; for Ireland, Leonard Kidd. Elections occurring as they do only at intervals of five years, it may not be superfluous to point out how and when this method of representation arose. It was in 1886 that the legislature recognised the reasonableness of giving to the practitioners of the country, whose fees maintain the Council, whose education is regulated by it, and whose names may eventually be erased by it from the Register, direct representation upon that Council. The Medical Act of that year directed that three representatives were to be appointed by registered practitioners in England and Wales, one by Scotland, and one by Ireland. In 1909 the G.M.C. recommended to the Privy Council that there should be a fourth representative for England, and at the next election in 1911 a fourth was added. At the elections of 1911 and 1919—the long interval being due to postponement on account of the war—the nominees of the British Medical Association were returned by large majorities. Under the original Act of 1858, the only members of the Council outside the representatives of licensing bodies consisted of six Crown nominees—four for England, one each for Scotland and Ireland. In 1886 the number of English Crown nominees was reduced to three. The first Crown nominees were :—For England : Sir James Clark, Sir Charles Hastings, (Sir) William Lawrence, and Thomas Pridgin Teale ; for Scotland, Sir Robert Christison ; and for Ireland, William Stokes. Since that time there has been a growing tendency for the Crown to take its nominees from the public medical services. Sir John Simon's appointment in 1876 has been followed by that of his successors in the position of chief medical officer to the Local Government Board or, more recently, the Ministry of Health. The same principle is now being observed in respect of Scotland and Ireland. The other Crown appointments in England have also taken on something of a representative character, one being chairman of the Central Midwives Board, the other connected with dentistry, until this became unnecessary in 1921 when the Dentists Act directed the appointment by the Privy Council of three dentists as additional members of the Council. It is manifestly useful that each of the great public services should have its authoritative exponent on the Council, while it is equally desirable that the practising members of the profession should have their mouthpiece in the Council chamber. The point of view of the practitioner is not necessarily identical with that of the colleges and universities, which commonly send consultants or members of the professorial staff to represent them. In point of fact, however, unanimity on questions of medical education, registration, and discipline has been so complete that it would be difficult for an ordinary onlooker to tell which member of the Council stood for the teaching bodies and which for the practitioners.

A LIST of the medical men who stood successfully for Parliament at the recent General Election will be seen on p. 987. We hope later to add the name of Sir George Berry to this list, and extend meanwhile our congratulations to the 11 medical Members of Parliament, who will no doubt again form themselves into a Parliamentary Medical Committee to watch over the interests of medicine for the benefit of the nation.

Annotations.

"Ne quid nimis."

MENTAL HOSPITAL ADMINISTRATION.

THE tenth annual report [1] of the Board of Control appears at a time when its intrinsic interest is greatly heightened by the evidence being given before the Royal Commission. The report deals with the year 1923 and makes observations on a number of points in connexion with lunacy administration to which reference has been made in our periodic survey of the Mental Hospitals Service. One of the chief anxieties of the Board, as its chairman, Sir Frederick Willis, assured the Commission, relates to the coming necessity of additional accommodation. The total insane population on Jan. 1st last amounted to 130,334, an increment for the year of 4055, which is slightly greater than the steady increase which has now been going on for several years. The number of vacant beds has been reduced by one-half, and at its present figure of 4754, allowing for inequalities of distribution, this means that overcrowding must already exist in some asylums, as indeed is actually the case. Alarming as this condition of affairs may appear, it does not indicate that the incidence of insanity in the general population is increasing, for this has remained remarkably constant for a large number of years ; the increase in the asylum population is rather due to the improved health of the certified insane, which is reflected in a fall of the death-rate from 8·89 per cent. to 7·71 per cent. during the year. The recovery-rate shows little change at 31·64 per cent. (calculated on the direct admissions). The weekly cost of maintenance of rate-aided patients has fallen by no less than 12 per cent. It is significant that the proportion of rate-aided patients to the total certified insane is increasing, a change for which more stringent financial conditions among the middle classes are no doubt responsible ; "private" patients, although among them are included large numbers in the "Service" class, amount to only 11·6 per cent. of the total. The report discusses at length the available means of providing further accommodation. The position can probably be relieved, at all events for a time, by other and less costly means than the erection of new hospitals, and if the suggestions made by the Board are carried out, the relief of congestion may well be accompanied by improvement in the conditions and amenities of existing institutions. These suggestions fall naturally into two categories. The aim of the first is a redistribution of the inmates, staff included. In many mental hospitals there is no separate nurses' home, and the provision of such a building would set free additional beds in the main building, besides improving the attractions of a nursing career in the eyes of possible candidates for the staff. There is a similar lack of separate admission hospitals and villas for convalescent cases. It is well recognised that treatment, apart from the chronic insane, is of advantage both at the beginning and at the end of a recoverable mental illness, and such reconstruction would therefore increase the resources as well as the mere capacity of the hospital which undertook it. The other category is concerned with accommodating certain of the insane elsewhere. There are many who might well be transferred to Poor-law institutions, to institutions for the mentally defective (if these existed), or boarded out under single care.

Favourable comment is made on certain details of administrative progress. There have been improvements in classification, in the encouragement of personal cleanliness, in the granting of freedom (whether within the asylum or on parole outside), in the provision of dental and other specialist treatment, in the provision of clothing and amusements and in dietaries. Occupational treatment is said to leave room for improvement, an undue number of patients appearing in the returns as being employed only in ward work. There is also a widespread lack of facilities for the isolation of infectious disease; where suitable buildings exist they are sometimes either unequipped or in occupation for other purposes. The fact remains that the average health of asylum inmates shows a marked improvement. No doubt the fall in mortality is due in no small part to the reduced incidence of tuberculosis, the number of recognised cases having fallen by several hundreds to the figure of 1288. There is very wide variation in the incidence of tuberculosis in different hospitals, and since the proportion of tuberculous inmates has been persistently high for a number of years in the same institutions, some explanation for this local variation must exist, as well as for the fact that the average incidence is still eight times that among the general population. Whether this is due to the "mental and physical peculiarities of the insane," to intra-mural ward infection, or to a deficient dietary, is still a matter largely of conjecture. Both dysentery and "severe diarrhœa"—which are now notified weekly, with much greater resulting accuracy in estimating their frequency—have diminished considerably, probably as the result of improved methods in dealing with foul linen, as recommended in a circular issued by the Board. Typhoid and paratyphoid, on the other hand, show little change, and it is a remarkable fact that women, among both patients and staff, appear very much more liable to attack by this disease than men. It is not suggested in the report that this discrepancy may be explained in part by persistence among the male population of the immunity conferred by war-time inoculation; indeed, no mention is made of this possible factor, although it would certainly appear to be one worthy of investigation. A long section of the report deals with original investigations which have been carried out during the year. Twelve mental hospitals have been engaged in research of various kinds, whether bacteriological, biochemical, or therapeutic. In the latter class are, of course, included a variety of attempts in various hospitals at the specific treatment of general paralysis. Much of this work has already been summarised in THE LANCET.

---

[1] H.M. Stationery Office. 10s. 6d.

Less cheerful reading will be found in the section of the report dealing with mental deficiency. Whereas the sins of omission and other peccadilloes of the public asylums are treated with a bland and almost apologetic consideration, the entire failure of certain local authorities to give effect to the provisions of the Education Acts with regard to mental deficiency is not unnaturally deplored in measured, but very definite terms. A contrast is drawn between a certain easily recognised Midland centre, where the organisation for dealing with defectives has been perfected to a high degree, and another town where it can be said hardly to exist. In the former case the ascertained defectives amount to 1·1 per cent. of children of school age, in the latter to 0·2 per cent., which does not mean that the latter town enjoys a singular freedom from mental deficiency, but simply that it has totally inadequate facilities for detecting it, apart altogether from any means of dealing with it after detection. The total "ascertainments" throughout the country amount to 35,413, but if anyone supposes that this figure anything like represents the number of defectives with which we have to deal he is unfortunately and greatly mistaken. "Ascertainment," either by officials or by voluntary associations, or by coöperation between local authorities, the managers of refuges, and the police, is sometimes almost entirely neglected. As regards disposal, in some large centres there are no special schools whatever; 33 local authorities have not placed a single case under supervision; 54 have not a single case under guardianship. The lack of large institutions for training is, of course, notorious. That the lives of defectives can be made happier and more useful and that many social evils might be averted by effective provision of this kind is perfectly well known, and unless more active steps are taken in the near future by certain local authorities, it may well be asked whether further legislation is not advisable to ensure that the provisions of the Education Acts shall be more effectively and more generally carried out.

ENDOGENOUS ALCOHOLURIA.

THE metabolism of alcohol has suffered a singular neglect at the hands of physiologists and biochemists. For this reason Prof. Heilner's review[1] deserves careful attention, particularly as he propounds an ingenious theory of his own based upon observations on the excretion of alcohol in the urine. He begins by discussing the importance of catalysts and enzymes in oxidising the intermediate products of metabolism, pointing out that such diseases as alkaptonuria and cystinuria are due to the absence of these bodies. Ketosis is also due to the derangement of some catalyst or ferment responsible for the final oxidation of fatty acids, although the antiketogenous action of carbohydrates remains almost unexplained. In 1908 Dr. Heilner suggested that alcohol, formed intracellularly from sugar, was able to act as a catalyst in the oxidation and breakdown of fatty acids, supporting his theory by the fact that endogenous alcohol was known to originate from normal carbohydrate metabolism. Thus in diabetes mellitus, the alcohol content is lessened in the tissues, while the administration of alcohol by the mouth lessens the excretion of acetone bodies in the urine. Dr. Heilner, however, regards the action of exogenous alcohol as being quite different from that of endogenous, which might be regarded as "nascent." According to him, the administration of alcohol, either subcutaneously or by the mouth, is followed by the taking up of this substance by the various tissues and organs, according to their particular "affinity." The alcohol is then drained from these tissues to the liver and muscles, where it is oxidised. Endogenous alcohol, on the other hand, is immediately oxidised in the cells in which it is formed. The only cells where this process goes on normally are those of the muscles and liver, and consequently these cells are not damaged by the process. Nerve cells, however, which, owing to their lipoid content, dissolve a large quantity of alcohol, are unable to produce or oxidise it, with the result that intoxication results from the exogenous variety. A series of experiments on rabbits are given in support of this view. Rabbits are easily killed by the administration of alcohol by the mouth, whilst the same dose administered intramuscularly merely produces mild symptoms of intoxication. These observations led the author to inject alcohol for the treatment of diabetic coma. He thought there might be a series of diseases due to the lack of a specific ferment or catalyst necessary for the oxidation of endogenous alcohol, which would then circulate, and, by its solubility in nerve cells, produce various nervous diseases. In the first place it was necessary to prove that no alcohol was excreted in the normal individual. This was demonstrated by a long series of urinary examinations of teetotal people, Widmark's method with modification being employed. Alcohol was not found in normal urines, but it occurred in a fair proportion of 50 cases from a psychiatric clinic. The average amount present was 0·15 part per 1000 of urine; in one case as much as 1·26 g. of alcohol was found in the 24 hours specimen. The patients were, of course, kept on a rigid diet, from which alcohol was excluded. The author next considered the question as to whether the origin of the urinary alcohol might not lie in fermentation of carbohydrates in the gut. This he negatived for various reasons, and deduced that its presence was due to the lack of some specific ferment. Finally, the catalytic action of alcohol in the oxidation of fats was examined; it was found that the production of endogenous alcohol increased when fat katabolism increased.

---

[1] Endogene Alkoholurie. Der Aethylalkohol als Zwischenprodukt. By Prof. Ernst Heilner. Münchener Medizinische Wochenschrift, Oct. 10th, 1924.

The author concludes that endogenous alcoholuria may play an important part in the ætiology of nervous diseases. Many arguments could be brought against Dr. Heilner's theories; the author puts them forward tentatively with a view to further investigation.

SHELL-FISH AND DISEASE.

THE connexion between diseases of the enteric group and polluted shell-fish is now clearly recognised, although it is only within comparatively recent years that this connexion has been definitely established. The passage of infected material into a river which carries the virulent bacteria down to the oyster-beds in its estuary is too well known a fact to need further elaboration. Despite the vigilance of sanitary authorities it seems almost impossible to prevent this entirely, and consequently interest settles round the detection of the oyster which has come from a polluted bed. How this may be done and how the health authorities on the one hand and the Ancient and Worshipful Company of Fishmongers on the other have coöperated to prevent the sale of disease-bearing shell-fish is described by Prof. J. W. H. Eyre in the current issue of *Public Health*. The principle involved lies in the fact that "disease-producing 'intestinal' bacteria rarely occur except in association with a preponderance of *Bacillus coli*," and hence an estimate of the safety or danger of any given batch of oysters can be demonstrated by a bacteriological examination for the latter organism. By mincing the interior of oysters and examining a fine suspension of this material in sterile water the number of colon bacilli may be estimated, following a difficult and complicated technique. Such an operation will, however, require many days for its completion, and from the point of view of the oyster merchant may be vexatious in the extreme. Consequently Prof. Eyre has elaborated a "short method" which permits an opinion to be given after 24 hours. Briefly, it consists of opening oysters with aseptic precautions and inoculating the liquor into tubes of bile-salt broth, of glucose broth, and of litmus milk in suitable dilutions. After 24 hours' incubation these tubes are examined and the presence or otherwise of the colon bacillus determined by observation of the usual changes in the media. If acidity and gas are present in the bile-salt broth culture, for example, this is held to indicate that the oyster from which it was derived contained *at least* 50 *B. coli*, and is therefore to be condemned according to a definite standard determined by the more complicated long method of analysis. If a certain batch of shell-fish is condemned it is the Company of Fishmongers which usually takes action, for under the existing regulations it is a cumbersome undertaking for the local health authorities to institute proceedings. The Company has autocratic control over the London fish market, and it is both the jealous guardian of the interests of the public and the protective patron of the oyster industry. A study of the incidence of typhoid fever in the area over which the Company principally exercises its control is a striking testimony to the work carried out, although factors other than a stringent supervision of the shell-fish industry have also to be considered.

Not only do shell-fish cause disease by harbouring virulent organisms, but they may also be responsible for attacks of urticaria, mussels sometimes giving rise to an acute form of poisoning. In connexion with the latter, two French authors, Fiessinger and Ravina, have recently described[1] a milder form of poisoning by mussels which gives rise to a benign type of jaundice. There is no sudden onset within a few hours of eating mussels as in the acute cases, but two or three days after the meal a mild jaundice develops with a slight enlargement of the liver, absence of bile from the stools and its appearance in the urine as in the ordinary catarrhal jaundice. These authors studied the effect on guinea-pigs of the injection of glycerine and alcohol extracts of mussels, and they report that microscopical examination of the liver in these animals showed definite degenerative changes in the hepatic cells, particularly in the centre of the lobules. They are unable to conclude whether the toxic substance which produces these changes is the same which gives rise to acute mussel poisoning, and it is interesting to note that their cases of jaundice represented single individuals who had eaten mussels in company with others who remained unaffected, while in the case of acute poisoning it is generally a group of persons eating mussels from the same batch who develop symptoms.

MASKING NAUSEOUS DRUGS.

Curare cito, tuto et jucunde. To cure quickly, safely and pleasantly was set out long ago by Asclepiades as the object of any medicinal formula. *Jucunde* has proved a hard problem, and the unpleasant taste of many drugs is still a grave drawback to their use, especially with children. In the United States a large number of the commoner drugs are now obtainable in the form of sweets, and while this may be a handy method of overcoming a difficulty, it is not free from objections, amongst which increased cost is one. This also applies to the use of cachets and the like, where there is often the added drawback of the child's difficulty in swallowing such things. A more satisfactory way of rendering physic palatable is to make the drug itself tasteless or pleasant tasting, a matter to which Dr. Bachem has given careful attention in a recent number of the *Munich Medical Journal*. A large number of substances were tested by the following method. The tongue was touched with some of the solution to be used in diminishing the taste of the drug, and the latter was subsequently placed on the tongue and the taste observed. The effects of the several phosphates of sodium on the taste of various drugs were striking. For example, disodium phosphate very greatly diminishes the bitter taste of veronal-sodium, and tablets called "Paranoval," containing 0·25 g. of each of these substances, are said to be nearly tasteless in aqueous solution. A 10 per cent. solution of disodium phosphate also greatly diminishes the bitter taste of a 1 per cent. digitalis infusion and of a 1/10 per cent. solution of strychnine nitrate. The bitter taste of tincture of aloes and of quinine hydrochloride was only slightly diminished by disodium phosphate, which has also hardly any effect on the taste of tincture of gentian, morphine solution, potassium bromide solution (20 per cent.), and a 10 per cent. solution of caffeine sodium salicylate. A 10 per cent. solution of acid sodium phosphate rendered a 10 per cent. solution of veronal-sodium practically tasteless, but, curiously enough, it had no effect in improving the taste of a 1 per cent. digitalis infusion or a 2 per cent. quinine hydrochloride solution. The taste of the latter, however, was rendered far less bitter when the acid sodium phosphate was used in 20 per cent. solution, and such a solution also improved the taste of strychnine nitrate, urotropin, 1 per cent. morphine, and caffeine sodium salicylate. Acid sodium phosphate has practically no effect on the bitter taste of tincture of aloes, and mitigates but little the unpleasant taste of saline substances, its own taste becoming appreciable.

Remarkably successful results were obtained by the use of tincture of eriodictyon (*Yerba santa*) in removing or diminishing the unpleasant taste of a great variety of drugs. With the exception of aqueous phenol and ferrous sulphate solutions, every unpleasant or bitter tasting substance investigated underwent a great improvement in taste. Even bitter principles such as tincture of gentian and tincture of aloes almost completely lost their bitterness. A very large number of unpleasant tasting drugs gave satisfactory results, including 0·5 per cent. phenol, although 2 per cent. did not show much improvement. Fruit essences also have a marked effect in diminishing or improving the unpleasant taste of drugs subsequently placed on the tongue. A so-called raspberry essence, consisting of a mixture of the actual distillate from raspberries, with spirit and small quantities of various esters, chloroform, vanillin, &c., was used and placed on the tongue. After the sharp taste of the essence had disappeared, the unpleasant tasting drugs were applied to the tongue, and a distinct improvement was observed in almost every case tried, even including 5 per cent. ferrous sulphate. Only a slight improvement was found with undiluted tincture of aloes, 2 per cent. phenol, and 10 per cent. potassium iodide. There was also a noteworthy improvement even in the sweet taste of sodium salicylate. Gymnemic acid (from *Gymnema silvestris*) has the remarkable property of removing the sweet taste of all substances, though other tastes are unaffected. For example, it causes a sweet orange to taste like a lime, and renders sugar tasteless. It is difficult to give a rational explanation of the physiological mode of action of these taste-suppressing substances, particularly in the case of the phosphates. The raspberry essence is very sparingly soluble in water, and readily soluble in lipoids, and so its effect in inhibiting the action of the sensory nerve endings is not so inexplicable.

THE PRACTITIONER'S RESPONSIBILITY FOR THE MENTAL PATIENT'S SAFETY.

A CORRESPONDENT asks if any further duty attaches to a medical practitioner when, having informed a lunatic's nearest relative that it is desirable for everybody's safety that he should be removed to an asylum and that he is a danger to the public while at large, they refuse to take any action. Should the practitioner himself, our correspondent asks, spontaneously inform the authorities, or conversely, if he allows matters to remain as they are, would he be held in any way responsible were a tragedy to occur?—The question seems to us to fall under three heads, according as it affects the patient, the public, or the practitioner. If the patient is likely to suffer through neglect of proper treatment, we doubt whether anything can be done beyond giving a report in writing to the relatives and disclaiming further responsibility. If there be danger to the public, much depends on the gravity of the case. Should it be merely a question of a public nuisance the previous course of action may suffice; but if there be a likelihood of injury or assault—such as when a paranoiac carried firearms—the practitioner should inform the relieving officer of the facts and leave the matter with him. If it be possible to secure a second opinion before taking this step it would reduce the responsibility. In such a case a careful record should be made at the time of all material facts. The practitioner will be protected against legal action if he acts with reasonable care and in good faith. But if he knows a person to be dangerous and not under proper care and neglects to inform the authorities, he would certainly be blamed by the coroner should a tragedy occur.

ANEURYSM OF THE SPLENIC ARTERY.

DR. E. A. Baumgartner and Dr. W. S. Thomas,[1] of the Clifton Springs Sanitarium, New York, have collected 40 examples of this rare condition from the literature of the last 50 years, including a case which recently came under their observation. The cases were evenly distributed between the sexes; 19 were males and 16 females, while in 5 the sex was not stated. In 31 the ages ranged from 20 to 60, with 9 in the fourth decennium, and 8 each in the third and fifth, while in 6 the age was not given. Endocarditis with embolism or localised infection was described in only about an eighth of the cases. In only four was there a history of trauma, and in six case reports it is particularly stated that there was no history or evidence of syphilis, and the Wassermann reaction was negative. No one definite cause could therefore be given as in the case of aortic aneurysm. As regards the symptoms, over half the cases had either gastro-intestinal or intraperitoneal hæmorrhages. The gastro-intestinal hæmorrhages may last several months or may terminate fatally at once after rupture into the gastro-intestinal tract. Intraperitoneal hæmorrhage, due to rupture, was fatal in all the 12 cases in which it was found. Although in 15 cases the aneurysm was the size of a hen's egg or larger, in only four was an epigastric tumour described. Pain has been noted either in the form of very severe abdominal cramp or of discomfort only in the epigastrium. In 32 cases the aneurysm was situated in the main trunk of the splenic artery, in seven in one or more of its branches, and in one, reported by Osler, in both the trunk and the branches. In only one case, which was reported by Hoegler in 1920, was a diagnosis made before operation or autopsy. The writers, however, are of opinion that a history of epigastric or upper abdominal pain, more or less gastro-intestinal hæmorrhage, an enlarged spleen, an epigastric tumour with a murmur, and anæmia should certainly point to a splenic aneurysm, though none of these findings should rule out an aneurysm of the cœliac axis. The prognosis is bad, but is much better after operation. Six cases were operated on and four of these recovered, the only recoveries made out of the whole series of 40 cases. Laparotomy should be performed as early as possible. The writers' patient was a woman, aged 48, who had had a history of indigestion all her life and three attacks of severe gastro-intestinal hæmorrhage in the year before death. X ray examination was not satisfactory, although it showed a large spleen. Operation was not performed, as the patient was in extremis. At the autopsy an aneurysmal sac was found in the splenic artery, measuring 9 cm. in diameter, which is probably the largest on record. This was all the more remarkable, as no epigastric tumour had been found during life. The wall of the sac was 1 cm. thick and was composed of dense fibrous tissue. The spleen showed chronic passive congestion and there was hæmorrhage in the stomach and intestines.

COMPARATIVE MEDICINE.

THE Section of Comparative Medicine which was inaugurated at the Royal Society of Medicine in July, 1923, now musters 191 members, of whom 127 are human practitioners and 64 are veterinarians. Prof. F. Hobday is the first veterinarian to occupy the presidential chair, and in his opening address delivered last month he expressed his gratification at the selection of a title to the section which covers everything pertaining to the diseases of the human and animal worlds, including those of fish, insects, and plants. There are, he said, many diseases intercommunicable between animals and man, many which are analogous, and many which show totally different methods of manifestation; the contrasts of the latter being not only between man and animals but between the different varieties of animals themselves. Of intercommunicable diseases, to mention only some which are common in this country, there are glanders, tuberculosis, anthrax, rabies, mange, ringworm, and trichinosis; for study on analogous lines there are such diseases as influenza, pneumonia, tetanus, internal parasitic affections, diabetes, cystitis, pyorrhœa, dental caries, many surgical operations, and the formation of cancerous and other tumours. An instance of startling difference in the power of infecting some species and failing to infect others is afforded by the great and fatal virulence of *Bacillus mallei* for man and the horse tribe, and the immunity possessed by the ox; per contra the ruminant and pig tribes are extremely sensitive to foot-and-mouth disease, the horse and ass are comparatively insensitive. The comparative immunity of the dog to anthrax, compared with the extreme fatality of this disease to other animals, requires explanation. There is, Prof. Hobday went on, comparative work to be done in every section; much can be mutually learned by comparison between the method of working which brings the desired successful result in the man or the animal, and between the symptoms caused by the same disease in each variety of patient. Flesh is flesh, whether of man or beast, and disease is the common enemy. The administration of anæsthetics, the splendid safety of present-day surgery, the study of therapeutics and pathology, even medicine itself, all depended largely on pioneer work done upon animal patients. He encouraged veterinarians to attend the other section of the Society whenever there was anything to interest them. A closer union of medical and veterinary science was needed in order to bring about the prevention and extinction of disease in many parts of the world.

ANTI-RABIC TREATMENT.

WE owe it to the late Lord Long that rabies is no longer an existing danger in this country, for no case of rabies in animals has occurred in England and Wales since December, 1921. In view of this encouraging fact the Minister of Health has decided that special arrangements for anti-rabic treatment in this country are no longer necessary, although a watchful eye has still to be kept on foolish attempts to introduce canine pets by aeroplane. Therefore the Ministry has issued a revised memorandum to the sanitary authorities on the procedure recommended to be followed in the event of persons being bitten by dogs suspected or ascertained to be rabid. Arrangements for anti-rabic treatment with carbolised vaccine, prepared at the Ministry's laboratory, may still be made with Prof. L. S. Dudgeon at the Department of Pathology, St. Thomas's Hospital, London, S.E. 1, but the cost of treatment and any other expenses must now be borne by the patient. In any case where the medical officer of health is satisfied that a person who needs anti-rabic treatment cannot pay for the treatment or stay in London at his own expense for the two or three weeks necessary for the completion of the course, he must at once represent the matter to the council or to the chairman of the council in order that the funds required may be provided by the council. The Minister of Health is prepared to sanction reasonable expenditure incurred by the council for this purpose. The lines on which first-aid treatment of persons bitten by dogs should be carried out, in areas where rabies is suspected, are set out in the memorandum as follows:—

> The wound should be treated as soon as possible with undiluted carbolic acid, undiluted izal or similar disinfectant. The disinfectant should be allowed to come into contact with all parts of the wound, and should then be washed out with water or dilute disinfectant. If no disinfectant of the kind is available, the wound should be thoroughly washed and irrigated with hot or cold water. Where it is possible to get the immediate services of a doctor the treatment should be placed in his hands. If the diagnosis of rabies in the dog is confirmed, or notice is received from the Minister of Health that the case should be regarded as one of rabies for purposes of treatment, the person bitten should be urged to secure specific anti-rabic treatment as soon as possible, no matter what local treatment has been applied to the bite. Arrangements for anti-rabic treatment should be made through the medical officer of health of the district in which the patient resides.

Persons bitten by stray dogs or by dogs exhibiting unusual behaviour should at once inform the police with a view to the necessary inquiries being made.

> By arrangement with the Ministry of Agriculture and Fisheries, the names of all persons known to officers of that department or to the police to have been bitten by dogs suspected of being rabid will be communicated at once to the medical officer of health of the district in which the bitten persons live. As soon as information reaches the medical officer of health that a person in his district has been bitten by a dog suspected of being rabid, the facts of the case should at once be reported to the Senior Medical Officer, Med. I, Ministry of Health, giving full particulars. The medical officer of health should await instructions from the Minister of Health before sending patients away for treatment.

A brief summary is given of the principles which should guide a medical officer of health in recommending specific anti-rabic treatment. The instructions for the medical officer of health laid down in the memorandum—which apply also to cases notified as occurring in any of the Services—would appear to demand a vast amount of correspondence between various authorities before specific treatment can be instituted in cases where the disease is not self-evident. We sincerely hope that they will not invalidate the final injunction as to the "importance of securing all possible expedition in the procedure."

THE LONGMANS BI-CENTENARY.

LAST year, when we celebrated our centenary, we called attention to the fact that certain firms connected with THE LANCET by the strong links that join the publishers of medical books with the producers of a medical journal, rejoiced in a still more venerable pedigree than our own. It is a pleasant duty this year to congratulate Messrs. Longmans, Green and Co., who have now been established in the publishing trade for 200 years. We have to thank this firm for many classics. The debt owed by medical men to their discrimination is evident if we consider only a few of their more famous successes. Gray's Anatomy, for example, first published in 1858, is now flourishing in its twenty-second edition. Bayliss on the Principles of General Physiology is a classic unlikely to be superseded, whereas Sharpey-Schafer's Essentials of Histology, Quain's Dictionary of Medicine and Watson's Physics are hardly less well established. Of more recent origin, but no less useful, are the Monographs on Physiology and on Biochemistry, edited respectively by Prof. Ernest Starling and by Prof. R. H. A. Plimmer jointly with Prof. F. G. Hopkins. In the October number of the *Edinburgh Review* Mr. Harold Cox sets out the history of Longmans, Green and Co., and, like most true stories of a family business, the narrative is absorbing. The present partners include members of the sixth generation of Longmans to control the firm; we offer them the congratulations of a stalwart younger brother who is precluded from jealousy of their seniority by the assurance that in a few more centuries, when each of us has really reached maturity, the difference in age will appear inconsiderable.

THE FUNCTION OF THE CORPUS STRIATUM.

IN dealing in our issue of Oct. 25th with the localisation of "sleep centres" we noted the lack of exact knowledge of the functions of the thalamus and corpus striatum. It was the publication of S. A. K. Wilson's paper in 1912 on the disease named by him progressive lenticular degeneration which focused the attention of neuropathologists upon the corpus striatum, a region of the brain the pathology and physiology of which had been hitherto almost an untouched field. It is true that isolated cases of the malady had been recorded earlier by Gowers under the name of tetanoid chorea, and that C. Vogt had formulated a syndrome of the corpus striatum, but it remains the fact that until 1912 practically nothing was known of the structural reaction of the corpus striatum to disease, nor of its symptomatology in these circumstances. Since this date Wilson's paper has acted as a potent stimulus to clinical and pathological investigation, and an abundant literature has grown up on the subject. Nevertheless, more problems of every kind have been raised for solution by these researches than have been solved. Our knowledge of the normal functions of the basal ganglia remains where it was, and while we now possess an extensive and minute knowledge of the morbid histology of the structures in question, there is still considerable uncertainty as to what elements in the various so-called syndromes of the corpus striatum actually derive from disease within it, and not from involvement of adjacent regions of the brain. Moreover, a considerable degree of quite unnecessary confusion has been imparted to the subject by the application of the term "pseudosclerosis" to examples of the disease described by Wilson. The word in question was coined in 1883 by C. Westphal to differentiate from disseminated sclerosis two cases which, while presenting a clinical picture akin to that of this malady, failed to show the underlying lesions in the nervous system. From this period up to 1912, various obscure, diverse, and incompletely elucidated conditions have been included under this heading, which, vague from the outset, soon became meaningless. Unfortunately, German writers now use it to describe cases of progressive lenticular degeneration, despite the fact that Westphal's cases were clearly not examples of this disease. In the current number of *Medical Science* F. M. R. Walshe reviews briefly the recent additions to our knowledge of progressive lenticular degeneration, and of its position in relation to the condition now known as pseudosclerosis.

Progressive lenticular degeneration is described as a fatal disease characterised by the development of tremor and muscular rigidity closely resembling those seen in paralysis agitans, by dysarthria and dysphagia, by spasmodic weeping and laughter, and a slight degree of dementia. Like other of the so-called extrapyramidal diseases, it does not present the loss of voluntary power and the alterations in the reflexes characteristic of lesions involving the pyramidal system. Pathologically, the lesion found by Wilson included bilateral degeneration and softening of the putamen and caudate nucleus, and a profound degree of hepatic cirrhosis. It is the latter feature which renders the malady so unique, and it is of interest to note that the cirrhosis is clinically latent. As is the case with every newly discovered nervous disease, experience reveals, during the course of years, that the clinical picture and the underlying lesion are subject to much wider variations than were at first recognised. In the present instance this is particularly the case with the lesions. Cases have been described in which involuntary movements of athetotic type have replaced tremor, and it seems clear that the so-called torsion spasm is a clinical variant of the disease. One case presenting muscular rigidity without any involuntary movement has also been recorded, and verified pathologically. In respect of the morbid anatomy of the malady, a considerable modification of our original conceptions has become necessary. Of the 30 cases which have come to autopsy, a condition like that described by Wilson has been found in 14. In the others much less gross changes have been visible to the naked eye, and microscopic examination has shown that a system disease of the corpus striatum is not in question, but that cellular changes and nerve-fibre degeneration may be present in the cerebral cortex, cerebellum, and brain stem. A secondary neuroglial proliferation, corresponding in intensity and distribution to the parenchymatous change, is also found. In every instance, despite variations in the nervous lesion, hepatic cirrhosis is constant. These variations in the microscopic picture, with the addition of an inconstant and obscure pigmentation of the cornea, are now made the basis by German neuropathologists for the differentiation of progressive lenticular degeneration, as described by Wilson, from "pseudosclerosis." It is stated that a diffuse and purely microscopic lesion and the presence of corneal pigmentation are characteristic of a disease "pseudosclerosis," and that the presence of a sharply delimited lenticular necrosis and the absence of corneal pigmentation are the features of Wilson's disease. There can no longer be any doubt, however, that these are purely artificial criteria. In unequivocal cases of Wilson's disease, widely diffuse nervous lesions and corneal pigmentation have been recorded, while Spielmeyer has shown that, despite variations in distribution and intensity of morbid change in the nervous system, the lesion is essentially the same in cases recorded under each heading. It is clear, therefore, that the term "pseudosclerosis" is both intrinsically bad and without practical value, and its persistent use has served but to add confusion to an already difficult problem.

Many attempts have been made to elaborate a notion of the normal functions of the corpus striatum from the analysis of the symptom-complexes resulting from its involvement by disease. The apparently strict limitation of the lesion in progressive lenticular degeneration, as originally described, raised hopes that a sound physiology of the corpus striatum might be erected in this way. Unfortunately, to localise symptoms in this structure is not necessarily to determine its function; the two problems are essentially distinct. We cannot safely argue from the rigidity of progressive lenticular degeneration that the corpus striatum normally regulates muscle tone, more especially in view of the evidence provided by the work of Magnus to the effect that this regulation is a function of brain-stem centres, nor may we conclude with Ramsay Hunt that because disease of the globus pallidus is associated clinically with tremor, this mass of grey matter normally inhibits a physiological tremor. Nevertheless, the discovery and description of progressive lenticular degeneration has marked the beginning of a notable advance in clinical and pathological knowledge, and may yet provide us with indications upon which additions to the physiology of the nervous system of equal importance may be built.

THE King has appointed Mr. Francis Desmond Donovan, L.D.S. R.C.S. Eng., Surgeon Dentist to His Majesty's Household.

DR. E. P. Cathcart, F.R.S., Professor of Chemical Physiology in the University of Glasgow, has been appointed into the vacancy in the membership of the Medical Research Council caused by the retirement of Prof. D. Noel Paton, F.R.S.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XCV.—TREATMENT OF ANGINA PECTORIS.

BY angina pectoris I mean an arresting form of cardiac pain, substernal rather than submammary, in which the patient is conscious of a sense of oppression or constriction which may reach a high grade of intensity, up to intolerable anguish. This pain has well-recognised lines of radiation, and is often induced by effort or emotion. There are in addition characteristic associated symptoms not invariably present, notably the sense of impending death and of acute misery accompanied by varying vasomotor disorders such as cold sweats and deathly pallor. These attacks are the response of an inadequate heart to stress, due either to physical effort or emotion. Another potent factor is an exaltation or over-sensitiveness of the central nervous system consequent on prolonged worry, anxiety, or loss of sleep.

General Régime.

The first essential in dealing with the patient is to explain the significance of the phenomenon, pointing out that the substernal discomfort going on to pain must be accepted by him as a peremptory order to halt and to wait until the distress has passed. More than that, it must be considered as a clear indication of the necessity for a careful readjustment of his mode of life. Except in some of the milder cases of angina minor, the wise course is to insist on complete rest in bed for a month, if this be possible. During that time there is full opportunity for careful and detailed examination. When there is a raised blood pressure the patient can be watched to see how far rest and freedom from worry will reduce the hypertension and at the same time the renal efficiency can be investigated, if this is considered necessary, and the important question as to how far the mode of life must be modified will come under consideration. Plans for the future must be made for his guidance both in regard to his mental and physical activities. They must deal especially with the pace at which he lives and works, his hours at business, and the amount of travelling done. Special attention should be paid to the manner in which the patient spends his leisure, and any unnecessary expenditure of energy in politics or philanthropy viewed with disfavour. For anginal patients it is essential that the week-ends should be a time of rest, and all responsibilities which involve either mental or physical effort on the Sunday should be forthwith vetoed. When the time has come to attempt a return to a more normal life, the patient must be warned of the danger of exercise or effort immediately after a meal, more particularly if it entails exposure to a cold wind. An early retirement to bed is often helpful, and the patient who spends a quiet hour or two reading comfortably in bed before falling asleep is benefiting both his mind and his body. It is well to have the bed and bedroom warmed, otherwise an attack is likely to occur on retiring. Some patients are very sensitive to the chilly sensation experienced in getting into a cold bed.

The general treatment outlined above is an attempt to lower the level of physical effort in order to reduce the strain on a damaged and inadequate heart. As to medication, the recognition of the particular ætiological factor present may serve as an indication. When there is good reason to suspect syphilis, and more especially if the W.R. is positive, mercurial inunction is to be recommended, combined with iodide of potassium in doses of 10 to 15 gr. thrice daily; and a course of salvarsan or similar preparations should be given intravenously. In a large group of patients the blood pressure is unduly raised and persists at a high level in spite of rest and freedom from worry and nervous strain.

Diet and Exercise.

The *diet* of these patients requires regulating. The total intake of food is usually too great. The food should be simple and small in amount; soups and gravies should be eliminated and little if any fluid taken with the meals. It is wise to diminish greatly the amount of meat, roast or grilled, and also any excess of starchy foods or vegetables liable to cause flatulence. A blue pill once a week or fractional doses of calomel given in short courses with a regular morning saline are to be recommended. Where there is any tendency to intestinal flatulence, dimol or kerol in capsules or sodium acid sulphate in gr. x. to gr. xv. doses are all useful. All patients liable to angina should be careful not to overload their stomachs; the meals should be small and a period of rest allowed subsequent to the meal before any effort is attempted.

Exercise.—The myocardium, like every other muscle, benefits by exercise, and it is important that the anginal patient should not be made more of an invalid than is necessary. In the amount of effort undertaken his own sensations must be his guide. He must be honest with himself and slow down or stop at the first indication of substernal discomfort. The more natural a life the patient can lead the better, and he should make a point of getting some exercise daily in the open air. He should, however, be chary of walking against a stiff wind, more particularly if the air be keen. This difficulty in taking as much or as vigorous exercise as formerly tends to induce obesity with the consequent added stress on the heart. When this tendency is noted, vigorous efforts must be made to keep the weight within normal limits. Any gouty tendency should receive appropriate treatment, especially the windy distension of gouty dyspepsia.

In many patients the outstanding factor is mental, the result of prolonged overwork, domestic worries, or business activities. In them the nervous system is on edge. Massive doses of ammonium bromide are then of undoubted value, gr. xx. thrice daily. This is especially useful in the first month or two of treatment, when the patient's habits and mode of life are being reorganised.

Drugs and Special Methods.

The iodides have already been mentioned as of value in the syphilitic group. If they are tolerated well it is worth while giving them a fair trial in the presence of frank arterio-sclerosis. They are usefully combined with bromides, arsenic, and belladonna. Iodine may with advantage be prescribed in the collosol form—2 drachms thrice daily. Theobromine, either as a pure drug in 5 gr. doses given four times a day, or as diuretin in gr. x. doses three or four times daily, appears to diminish the liability to pain. The diuretin is more pleasant when prescribed with the syrup of ginger. If there is any tendency to anæmia or general debility simple hæmatinics combined with arsenic are of undoubted benefit when taken over a long period, the object being to improve the condition of the myocardium by supplying it with good blood.

Diathermy is a method of treatment which is on its trial, but there can be no doubt that it frequently makes patients more comfortable; it appears to diminish both the frequency and the severity of the attacks of anginal pain, though the effect on the blood pressure in patients with hypertension is not very dramatic. It should be administered in a dose varying from 700 to 1500 milliampères, for 20 to 30 minutes twice or thrice a week, the electrodes being placed one on each arm, or one over the præcordium and the other between the shoulders.

On the first indication of substernal discomfort a tablet of trinitrin slowly chewed frequently aborts the attack, and it is advisable to anticipate and ward off a seizure by sucking a tablet before going out into the cold air.

Treatment During an Attack.

In many instances the inhalation of amyl nitrite rapidly diminishes the severity of the pain and relieves the distress. This is, however, not always the case, nor, even when the pain is mitigated, is the effect persistent. If the vaso-dilators fail and the pain persists then there is no drug comparable to morphia. It should be given in sufficiently large doses to bring relief and should be combined with gr. 1/50th atropine. It is essential that the pain should be eased. In persistent angina the action of the hypodermic should be sustained by opium given as a draught. Chloral, gr. x. to xv., combined with this draught is also useful, or chloral may be taken twice a day instead of the opium for a few days at a time. If the pain is agonising and resistant to morphia, a general anæsthesia by the administration of chloroform is justifiable. In the earlier stages of the attack a rapid carminative is often most comforting. Brandy or whisky taken only slightly diluted will often be followed by the eructation of wind and consequent relief. A strong menthol draught is often more efficient. For example:

℞	Mentholis	gr. viii.
	Spts. ammon. co...	aa ℥i.
	Spts. chloroformi..	
	Tr. zingiberis	

Two teaspoonfuls in water taken as strong as possible.

The tendency to nocturnal attacks is often obviated by a draught of nepenthe washed down with an ounce of whisky in water before retiring.

Conclusion.

It is clear that in the management of this condition, except in the acute anginal seizures, the object of treatment is to prevent undue stress upon a depreciated myocardium. The pathological changes are incurable. The victim has to face his limitations and live within them. He has to learn to regulate his life and to live at a level of physical and mental effort compatible with his disability. But while recognising this, every means must be used to maintain the myocardium at the full power of which it is capable by a carefully regulated life and by medicinal and other measures.

JOHN HAY, D.L., M.D., F.R.C.P. Lond.,
Professor of Medicine, Liverpool University; Senior Physician, Royal Infirmary, Liverpool.

Medicine and the Law.

REX *v.* HADWEN.

THE trial of Dr. W. R. Hadwen at Gloucester, on a charge of manslaughter, arising out of the death of a child, his patient, merits close attention by reason of the rarity with which criminal charges, based on negligence, are brought against medical practitioners, and by the consequent importance of a full understanding of the circumstances in which Dr. Hadwen was tried and acquitted. The essential facts, the symptoms alleged in the witness-box to have been observed by those who gave evidence for the prosecution, having seen little Nellie Burnham when alive, the views expressed by those who did not so see her, the facts alleged, and the views avowed by Dr. Hadwen, will all be considered and weighed by our medical readers, who will form their own opinions as to whether the child died of diphtheria or did not suffer from it at any time. The latter was the contention of Dr. Hadwen and of counsel who defended him. It was not, however, necessary for the jury to state, or even to formulate, a conclusion as to this. They did not have to answer a series of questions as in a civil action. It was enough for them to say "Guilty" or "Not Guilty," in accordance with the judge's instruction as to the law, and their own interpretation and application of the facts before them. As Mr. Justice Lush's summing-up can be read in the Special Supplement to this issue, it is not necessary to refer here otherwise than briefly to the law governing manslaughter in the case of a medical practitioner charged with having caused the death of a patient by negligence. Charges of manslaughter by negligence are not uncommon, occurring as they do, for example, in cases when a motorist causes the death of a pedestrian or other person through reckless driving. If such a one, however, is convicted, it is because he has been proved guilty of more than mere carelessness, or lack of observation, or bad driving. He has been proved to have been recklessly and "criminally" negligent. As the judge who tried Dr. Hadwen told the jury in his summing-up, the case required strong and clear proof by the Crown that there had been "criminal" neglect. Moreover, the jury were not to say whether Dr. Hadwen's views were those of a wise medical man or not. Again, it was not enough for the Crown to prove that if the doctor had been careful the patient would have "had a chance." They must be satisfied that he had been careless, and that "in all human probability" if proper care had been used the child "would have recovered." There must, in short, be a much stronger case of negligence than in a civil action for negligence. Unless the negligence were of so gross a character as to amount to "wicked negligence" it would not justify a conviction for manslaughter.

The precise bearing of Dr. Hadwen's expressed opinions upon subjects which the medical profession at large accepts as facts was defined by Mr. Justice Lush. He regarded it as "very unfortunate" that a doctor should shut his eyes to matters generally accepted in his profession, but the jury were not there to criticise his views. He was allowed to follow the medical profession and even if he held peculiar views and at the same time acted as he considered best, he would not be guilty of culpable neglect, although he might be said to be "terribly and sadly mistaken." It will be observed from this that if the jury had been convinced that Dr. Hadwen ought to have taken a swab of Nellie Burnham's throat or to have used antitoxin, it would not necessarily have involved any obligation to convict him of manslaughter, unless they were satisfied that he had no honest belief that such omissions were wrong. If they thought that he honestly held the views he expressed he was in a different position from a man who made the same omissions from sheer carelessness, or, for example, from attending his patient when he was intoxicated. Fom the above it will clearly be seen that in view of the law the prosecution se themselves a difficult task in endeavouring to secure Dr. Hadwen's conviction upon an indictment for manslaughter, however undesirable his treatment of his patient may appear to other members of the medical profession. It was for the jury to hold that the conduct of the accused amounted to crimina misconduct, and also that it occasioned or accelerated death.

With reference to the conduct of the case for and against Dr. Hadwen, it will be seen that an objection was made by his counsel, Sir E. Marshall Hall, to evidence being given as to the result of the examination of the swab taken from the child's throat. This was on the ground that an envelope labelled "N. Burnham," in which the swab had been sent for examination, had been destroyed, and that therefore the swab examined was insufficiently identified. The evidence was admitted, but the judge advised that such envelopes should be kept, and medical men will note the necessity for strict identification and record as to any articles which may be destined to become exhibits in legal proceedings. Another point, as to which protest was made by the defence, in which protest the judge concurred, was the fact that Dr. Hadwen was not invited to be present at the post-mortem examination. There is no obligation as to this, nor is there any prohibition, in the Coroners Act, 1887, which, however, contains the following passage[1] in the section regarding post-mortems: "Provided that where a person states upon oath before the coroner that in his belief the death of the deceased was caused partly or entirely by the improper or negligent treatment of a medical practitioner or other person, such medical practitioners or other persons shall not be allowed to perform or assist at the post-mortem examination of the deceased." This seems to allow, or at any rate not to forbid, the attendance of the accused medical man, but merely in the capacity of an interested spectator with no power to interfere in any way.

The Venue of the Hadwen Case.

A legal correspondent writes as follows:—The unsuccessful attempt to remove the Hadwen trial from Gloucester to London illustrates a queer inconsistency of our law. On the one hand jurymen are directed to hearken to the evidence and are sworn to give a true verdict in the light of it, all hearsay testimony being carefully excluded. On the other hand, the accused person is entitled to be tried in the place where he is known. Venue, it may be unnecessary to explain, is the area of proper jurisdiction for trial of a crime by indictment. The initial Latin words of an ancient writ (now abolished) directed the sheriff to "make jurors come" to a particular place. The venue is the coming, the place to which the jurors come. Another expression used almost as a synonym for venue in early times is "visne," a word connoting vicinity. The jurors are men of the neighbourhood where the supposed crime is committed; and when in the old legal phrase a man who pleads "not guilty" is said to put himself upon the country (*ponit se super patriam*) his *patria* is not his fatherland but his own countryside. The explanation is historical. If the pedigree of our jury system is traced back far enough, the jurors are found not to be mere silent listeners and verdict-givers, but active investigators and actual witnesses who are directed to declare the common report of crimes in their neighbourhood. They are summoned not to hear all about the case and to decide accordingly, but because they know everything about it already. Until modern times, as is well known, a prisoner was not allowed to call witnesses. This restriction, which we find so monstrously unjust, perhaps was less remarkable in days when the jurymen themselves collected and presented the evidence. Be that as it may, an immemorial tradition has established the broad principle (subject to certain well-recognised modifications) that a man is to be tried in the place where he is known and where the evidence is available. In 1856, by what is known as the Palmer Act, Parliament permitted cases to be removed for trial to the Central Criminal Court "if it shall appear expedient to the ends of justice." Applications for removal are rare. On the one side accused persons are usually content to be judged on the spot, and it is often inconvenient for their legal advisers to go further afield; on the other side the Crown cannot apply to shift the venue without creating the impression of loading the dice against the accused. Nevertheless, the King's Bench Division does permit the removal either where a provincial jury will have to go and view premises in some other county, or where it is believed that a fair and impartial trial cannot be had in the jurisdiction in which the venue is laid.

---

[1] Section 21, subsection 2.

This being the law, let us see what happened on the application in Dr. Hadwen's case. Up to a certain point the court was sympathetic; there was, at any rate, a case for argument. The difficulty was that the court was asked to contemplate first a state of acute local feeling and secondly the prospect of a forensic atmosphere which would prejudice a calm trial—two matters remarkably difficult to prove by affidavit in face of the excellent British tradition that it is more important that an accused person shall have his full rights than that the Crown shall secure a conviction. In dismissing the application the Lord Chief Justice gave a reason which many lawyers find unconvincing. "I cannot believe," he said, "that there cannot be found in Gloucester 12 persons who, whatever their view on other matters, will give a true verdict on the indictment." With profound respect to his Lordship the statement is irrelevant. Nobody doubts that hundreds of impartial persons could be found in Gloucester. Jurymen, however, are not selected after a search for impartiality but by a more haphazard method. Mr. Justice Avory agreed with the Lord Chief Justice, but Mr. Justice Clavell Salter observed that if he had to deal with the matter alone he would have taken the opposite view. "I feel some fears on the matter, which I hope will prove unfounded." When one reads of the atmosphere at the Gloucester trial, the crowds assembled not out of mere curiosity, but from partisan motives, the court packed with supporters of the accused, the hand-clapping and applause at any point which appeared to assist the defence, one may readily feel that the judicial fears proved all too well founded.

Special Articles.

THE HEALTH OF MERCHANT SEAMEN.

BY W. E. HOME, M.D., B.Sc., D.P.H.,
M.R.C.P. EDIN.,
FLEET SURGEON, R.N. (RETIRED).

CONCERNING merchant seamen, their health, the diseases that occur amongst them, and their death-rate as a class, there is no accurate knowledge. Something can be learned from the annual reports of the medical officers of health to port sanitary authorities, but the only information covering the whole ground is in the statement of the causes of the deaths of seamen which was published annually before the war by the Board of Trade. The war cut across all routines, but in 1920 the Board presented a "Return of the Deaths of Seamen and Fishermen reported to the Board of Trade in the Year ended 30th June, 1914," and, in the early part of this year, it issued a "Return of Shipping Casualties to and Deaths on Vessels Registered in the United Kingdom," which covered the years 1919, 1920, and 1921; this later return, particularly as it refers to 1921, may be profitably discussed. The return states the number of deaths from injury and disease in the Merchant Marine reported during 1921. This total is, of course, important and essential, but by itself insufficient. What the medical profession wants to know is not so much the deaths as the death-rates, and it does seem surprising that this return should neither supply these itself nor furnish the appropriate figures from which they could be calculated. There is a real difficulty. Figures of the total numbers of men employed from day to day in the Merchant Marine do not exist, but the Board does supply, to quote its own words, "figures (which) show the numbers of persons forming the first crews of vessels actually employed during the year specified, and furnish an approximate basis for estimating the variations in the extent of the risks." But then, unfortunately, that is just what the figures presented do not do. The number for 1921 is some 274,000, but that includes fishermen along with the men in trading vessels, who are the men generally known as "merchant seamen," and this figure, 274,000, does not enable us to calculate a death-rate for either. As a matter of fact, the Board of Trade gave me at once any figures asked for, so it has been possible to work out something like the wanted death-rates; but what real use to the world is such a return without the death-rates already worked out and with those of previous years for comparison?

The first table in the report that concerns us as medical men is Table VI., Deaths by Injury; these deaths are arranged in many classes and columns, at considerable expense for printing, according as they occurred in sail or steam, among British, foreign, or lascar seamen, or to masters, stewards, &c., but with never a statement of the total number of men in any one of the groups mentioned. Table VII. shows the deaths by disease reported amongst members of the crews of trading vessels, Table VIII. tells which of the deaths enumerated in Table VII. occurred after the patients had been discharged from their ships, and Table IX. shows the number of deaths to which drink was a contributory cause, and in each of these three tables the deaths of British, foreign, and lascar seamen are stated in separate columns, but again without any statement of the approximate numbers in each group.

"Whitaker's Almanack" is our great authority on the bureaucracy by which we are governed, but no medical officer can be found in "Whitaker" attached to the Board of Trade in any position which might give him oversight of these returns of deaths, and the returns themselves seem to bear witness to their origin under purely lay control. The diseases which were the causes of the deaths are arranged in eight groups. Group A, Specific Febrile Diseases, includes beri-beri, contrary to present practice. Group B, Constitutional Diseases, is rather a surprise, as that name for a group is almost forgotten. In the Navy health reports it was last used in the report for 1885, 40 years ago! Here it includes tuberculosis of all kinds, and cancer! It is somewhat astonishing that the Board of Trade should not have anyone to tell them that tuberculosis is an infectious disease, or that, knowing it, they should class it as constitutional.

It is probably an accident that this return of deaths is made by the Board of Trade. Other returns were supplied by the ships' captains, and somebody had to get the report of the deaths which had happened on the voyage, and therefore the captains would find it most convenient to send the death reports, with the others, to the Board of Trade. So the Board gets the figures, and, no doubt, worries a bit to see they are accurate, and then publishes them, for which we are grateful. The Board then ceases to worry. If the figures referred to bags of coffee or tons of coal, that would be all right; it would be to the financial interest of certain people to keep a watchful eye on the returns. But deaths of seamen are nobody's concern, and I urge that there ought to be somebody appointed to see that these figures are considered when submitted, and properly put before the profession and the country, and thus enabling them to be used for the benefit of the seamen. This can only be done by the

Ministry of Health, but, until it takes hold of the reins, who else is there to take the matter up except the National Sailors' and Firemen's Union, or some similar body?

As anyone studying these returns will first want to compare them with the similar figures published by the Navy, it would be very convenient if the method of grouping diseases adopted in the annual report of the health of the Navy (practically the same as that adopted by the Army) was followed by the Board of Trade here. In the table herewith I have endeavoured to classify the diseases, as far as possible, on that method. From this classification it will appear that in 1921 the death-rates were, in the Merchant Marine, for British seamen, 4·98 per 1000; for lascars, 6·72; and for foreign seamen, 8·41. The death-rate in the Navy was 3·57, in the Army 4·30. These figures, of course, include deaths from accidents, but the death-rates from disease alone were: British seamen, 2·08; foreign seamen, 3·16; lascars, 4·67; Navy, 2·00; and Army, 2·77.

1921.—Deaths and Death-rates in the Merchant Marine, Navy, and Army.

—	Deaths.			Death-rates.

† < =less than.

When considering the diseases of seamen, it is important to remember Dr. W. M. Willoughby's statement at the Congress of the Royal Sanitary Institute at Liverpool, that most of the diseases seen in ships come from the shore, and that, consequently, sailing ships (with longer time at sea) are healthier than steamers. To take, first, the death-rates of British seamen, we see that their enteric fever rate is higher than that of any other group. The pneumonia rate is the highest, and it is perhaps worth noticing that all the deaths from pneumonia were reported as occurring in steamships in 1921. Pneumonia is considered by the directing staffs of the Navy, Army, and Air Force to be a communicable or infectious disease, not a disease of the lung, and it is a pity it is not included by the Board of Trade in the A group, although it certainly is grouped still by the Registrar-General with the diseases of the respiratory system. All persons who deal with the health of numbers of men are coming to look on the incidence of pneumonia as a test for conditions of overcrowding. The death-rates for pneumonia in the Mercantile Marine were: British seamen, 0·32; foreign seamen, 0·51; lascars, 1·16; in the Navy, 0·31; and in the Army, 0·53. Attention should here be drawn to the fact that British and foreign seamen are required to have 120 cubic feet of air space in their ships, but lascars need not have more than 72, and that, in fact, they do have a much higher death-rate from pneumonia than have the others who are less closely crowded. A similar state of affairs becomes evident when we turn to the tuberculosis death-rates; these are in the Mercantile Marine: British, 0·15; foreign, 0·19; lascar, 0·62; in the Navy, 0·28; and in the Army, 0·24. The lascars with the smallest obligatory cubic space have far the heaviest rate. The other heavier death-rates for British seamen are due to: Diseases of the circulatory system, 0·32; alcohol, 0·24; and injuries, 2·41. Foreign seamen suffer severely, as already said, from pneumonia (0·51); they have also high death-rates from suicide (0·32), alcohol (0·25), and injuries (4·62). Lascars have the highest death-rate from suicide (0·33). The death-rate of lascars is obviously excessive, but the death-rate of British merchant seamen from disease is not far removed from that of the men in the Navy on the figures. But as the Board of Trade itself, as we have seen, remarks, we have only an approximate basis for estimating these rates. In the Navy and Army the number daily victualled is known, and the death-rates thereon calculated are accurate. In the Merchant Service we have only the figures of "the first crews of vessels" to go by, and these give us figures that would only be exactly comparable with those of the Navy, if all the ships were running on the New Year's day, and continued in steady employment all through the year, which they do not. The result is that every interruption makes the number of men given too high, so the death-rates are steadily lower on paper than they are in reality. The rates cannot be less than those in the table, but they may be a great deal higher. The true death-rates of the Merchant Service cannot be really known until the collection of the statistics is laid as a duty on the Ministry of Health, when an inspector, inspired by a knowledge of the value and importance of death-rates, would set himself to find out what the figures should be; he will not find the work, once he sets himself to it, nearly so difficult as it perhaps appears. The work should not, at any rate, be left in the hands of th Board of Trade, which is not staffed to appreciate what these figures mean, nor to do anything with them for the benefit of seamen, even when they are known.

McGILL UNIVERSITY, MONTREAL:
THE NEW PATHOLOGICAL BUILDING.

THE new pathological institute at McGill was opened by the Hon. N. Perodeau, Lieut.-Governor of the province of Quebec, on Oct. 6th, the 180th anniversary of the birth in Glasgow of James McGill, founder of the University. McGill died in Montreal in 1813 and left his estate there and £10,000 to establish a University, making the condition that this should be effected within ten years of his death. Prolonged litigation with the family led to much delay. A Charter was obtained in 1821 and in 1823 five professors were appointed, but no funds were available and there was no teaching. It was the existence of a private medical school, organised by the medical officers of the Montreal General Hospital, which relieved the University from this impasse, for in 1829 it was agreed that the Montreal Medical Institution should be "engrafted upon the College as its medical faculty." Which being done, the University came into actual existence, the medical faculty being by far the most important part of the organisation for the next 25 years or so; the arts faculty was established in 1843 and the faculty of natural science in 1857. The first degree granted by McGill was given in medicine in 1833. The medical school was for many years housed in the town, and it was not till 1872 that it obtained a building in the University grounds. Successive extensions were made from time to time and a splendid set of buildings is now completed by the new pathological institute.

History of Pathology at McGill University.

In this medical faculty pathology has always held an honoured position. In the middle of last century the clinical staff had largely been brought up under Scottish influence, and morbid anatomy was carefully cultivated and specimens were collected for teaching purposes in relation to medicine and surgery; some of these are still in the museum. This autopsy work was a distinctive feature of McGill and contrasted with the practice of American schools at the time when post-mortems were usually cursory or hardly performed at all. On this groundwork systematic independent teaching and research was implanted by Osler, who, in the 'seventies, came back from a trip to Europe full of enthusiasm and admiration for Virchow and his methods and started classes in pathological anatomy and histology (originally held in the cloak room) as part of his chair of the institutes of medicine. The chair of pathology was founded in 1892, and Dr. J. G. Adami, now Vice-Chancellor of the University of Liverpool, did much as first professor to enhance the reputation of McGill in the pathological world till he was succeeded ten years ago by Dr. Horst Oertel, under whom the department has reached its present imposing dimensions.

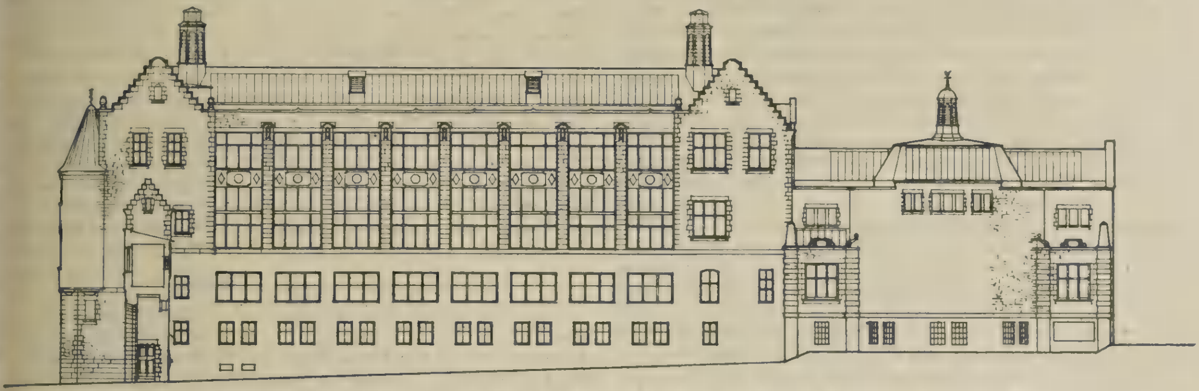

FIG. 1.—Elevation to courtyard of the new Pathological Institute at McGill University.

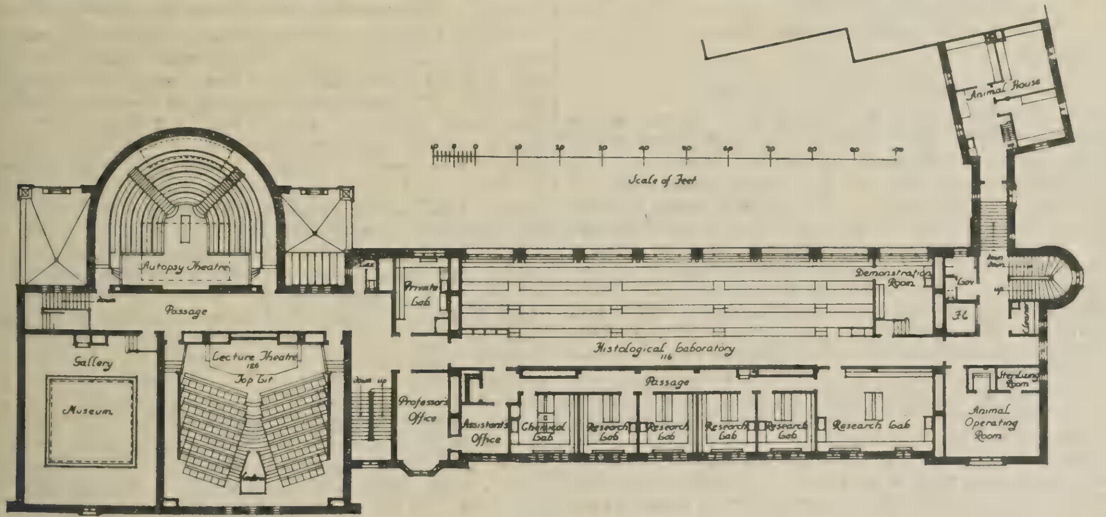

FIG. 2.—Plan of the second floor of the Institute.

The governors' minute-book records that at the momentous meeting in 1829 the room was filled by "numerous and respectable individuals who had assembled to witness the ceremony. Among the company was noticed several Members of the Government, the principal members of the Bar, the lecturers at the Montreal Medical Institution, and several gentlemen more or less connected with the proposed College." Much the same might be said of the present occasion, and there were in addition a number of delegates and representatives from other universities. The dedicatory address, which we shall print in a later issue, was given by Prof. A. E. Boycott.

The New Building.

The new building, a small part of which houses also medical jurisprudence, has been erected with funds subscribed for the centenary celebrations by the citizens of Montreal and the alumni of the University; large contributions have also been made by the Royal Victoria Hospital, and the whole is part of a scheme for the encouragement of the medical sciences which the Rockefeller Foundation has most generously helped. The total expenditure on construction and equipment has been a little more than £100,000, or about 2*s.* 6*d.* per cubic foot; the annual budget is estimated at about £13,000. The institute forms a handsome stone building in harmony with the rest of the University, and with the Royal Victoria Hospital, with which it is connected by a subway. Over all it measures about 240 by 70 feet, and this shape secures admirably the efficient lighting, without which a good proportion of a series of laboratories may be practically wasted.

The basement houses the machine room with the cooling plant, &c., the mortuary and chapel (approached both from the hospital and by a separate entrance at the rear of the building), preparation and mounting rooms for museum specimens, students' rooms, and cloak rooms. On the ground floor the visitor is reminded "hic est locus ubi mors gaudet succurrere vitae," and finds the lecture theatre (where porous acoustic tiles most successfully damp any reverberation), a museum, a large demonstration auditorium with two smaller autopsy rooms, a room for the pathological conferences between clinicians and pathologists which are so universal in America, the laboratories and record room for post-mortem and surgeons' specimens, general experimental rooms, and the library. The first floor provides an exceptionally well-lighted students' histological class room, a number of small research laboratories and animal accommodation, while the top floor is occupied by the subdepartment of bacteriology with a large class room and laboratories for routine work and research. Electricity, gas, hot and cold water, and compressed air are carried throughout the building; refrigerating pipes, live steam, and a vacuum are widely distributed. The floors are covered with linoleum on concrete. The whole forms an admirable roomy building in which the pathological work of McGill should flourish still more. It has not been possible at present to make as much accommodation as could be wished for chemical and experimental pathology, but the plans have been so drawn that these extensions may be added later at the north end of the building. We wish Prof. Oertel and his colleagues a happy occupation and a fruitful and prosperous enjoyment of their splendid home.

BERLIN.

From our own Correspondent.)

General Paralysis among Jews.

In the *Zeitschrift für Rassenhygiene* Dr. Bluhm, of Munich, recently reported an investigation into the incidence of general paralysis of the insane among Jews. He stated that of the insane Jews in the Munich asylums 21 per cent. suffered from general paralysis, the percentage among other insane persons being 13. In Eastern countries where Jews marry at an early age the disease is said to be less frequent amongst them. The reason of the greater frequency of paralysis is, in the author's opinion, that the brain of the Jew offers less resistance to syphilitic infection owing to the greater vivacity of the race and the racial preference for life in towns where there are more excitements than in the country; also there is a greater percentage of intellectual workers amongst the Jews. In the Jewish race paralysis usually breaks out at an earlier age than among other races. The disease runs a longer course in Jews than in others, but the duration of life is the same. It is remarkable that of the paralytic Jews 14 per cent. were habitual drunkards, against 11 per cent. of other paralytic patients; this is the more remarkable as alcoholism is less rife among Jews than amongst Gentiles; it seems to mean that a Jew indulging in spirits is especially liable to become paralytic. There is also a difference in the type of paralysis occurring in Jews; the demented form among Jews has an incidence of 31·8 per cent., compared to 74 per cent. in non-Jews; in the depressive form the percentages are 22·7 and 8 respectively, the agitated form 9 per cent., compared to 2 per cent., the megalomanic 25 per cent. as against 12 per cent., while atypical forms in Jews have a percentage of 11·4, compared to 4 in Gentiles. The most striking difference, however, is found in the relative percentages among women, being only 4 per cent. in Jews, but about 30 per cent. in others. The reason is probably that prostitution amongst Jewish girls in Germany is very rare. The author gave also interesting records concerning insanity amongst Jews in general. In the period of 1908 to 1920, 87,486 insane were received in the asylums of Bavaria, of whom 1373 were Jews, being 1·57 per cent. of the total number, whilst Jews number only 0·85 per cent. of the population in Bavaria.

Dogs as Guides for Blind Invalids.

A training school for dogs as guides for blind invalids of the late war was established some time ago. In that school dogs are trained to lead the blinded men through crowded streets and to avoid vehicular traffic. In the training ground of the school are dummy obstacles such as stairs, wire, stones, holes, bridges, and letter-boxes. After a training of six weeks a dog is, as a rule, able to lead a blind man. To accustom a dog to his companion and vice versa, the blind stay for a fortnight on the premises of the school, where rooms and nurses are provided for them. It is indeed striking—and touching—to see those dogs leading blind invalids safely through the streets, guarding them from traffic dangers.

Advertisements of the Medical Press.

The Union of the Medical Press recently held a conference on the occasion of the meeting of the Association of German Medical Men and Naturalists at Innsbruck. After a discussion concerning the agreements between medical authors and the press the conference discussed the question of advertisements of proprietary medicines. It was agreed that advertisements ought not to be received in the medical press without a statement of their ingredients, and in the case of compounds of strong action a statement of the proportion of ingredients had to be given. Advertisements making misleading statements of the chemical composition of the medicament, its efficacy, or its harmlessness were to be refused.

Discussion on Cerebral Tumours.

Before the Munich Medical Society Prof. E. Boström recently read a paper on cerebral tumours, basing his remarks on 72 cases that had been observed by him. The mortality of operated and of unoperated cases had been the same. The best chance of a cure was given by an early diagnosis. Operations for cysts gave favourable results. Headache was prevalent in 50 per cent. of the cases only, choked disc in 25 per cent. Radiographic examination was of value only in cases where a growth occurred in connexion with a bone and in cases with increased cerebral pressure, where the radiogram showed an expansion of the sutures of the skull. In the discussion which followed Prof. F. Sauerbruch stated that the results of an operation were not very favourable in his experience; radical removal of a cerebral tumour had been possible only in seven cases. Apart from the great difficulties of diagnosis and of localisation untoward results were frequent both during and after an operation. A number of patients showed, after the skull had been opened, symptoms of paralysis of respiration and of circulation. Pneumonia due to food entering the air passage owing to the disappearance of reflexes was frequent. The technique of the operation itself was relatively simple, but as the skull opening had to be rather circumscribed a view of the growth was difficult to obtain and was hindered also by the profuse hæmorrhage connected with the operation. Prof. Sauerbruch declined to perform ventricular puncture as devised by Dr. Neisser, because of the possible sequelæ of hæmorrhagic infarcts and lesion of the middle meningeal artery. To be effective the puncture had to be performed in different parts of the brain. Exploratory craniotomy on the principles of explorative laparotomy was to be recommended. Death from increased cerebral pressure might occur, but this happened only in the case of large and malignant growths which would be otherwise fatal even without exploratory craniotomy.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

TWO LARGE SEAPORTS.

THE following table gives some of the principal statistics for the cities of Liverpool and Glasgow for the year 1923:—

Name of city.	Estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Resp. diseases with influenza.	Neonatal mortality.	Infant mortality.	Maternal mort. from childbirth.
Liverpool ..	837,600	24·7	13·6	1·6	1·1	3·4	32	99	3·0
Glasgow ..	1,041,400	25·6	14·3	1·5	1·2	2·3	35	89	6·5

Liverpool.

Dr. E. W. Hope says that in Liverpool a larger proportion of the inhabitants seek hospital assistance in times of sickness than in any other city in the country, a fact which bears testimony to the public confidence in the institutions provided by the municipality and the boards of guardians. Latterly, under existing housing conditions, the claims on these institutions have increased. One of the events of the year was the opening on Dec. 15th of the Carnegie Welfare Centre by Miss Haldane, one of the trustees. Photographs and a description of the new centre are included in the report, and it is already proving a most valuable addition to the maternity and child welfare scheme. Photographs are also included in the report of the new seamen's dispensary, which was opened by the Lord Mayor of Liverpool in January, 1924. The site is admirably chosen for the work. The dispensary is intended to deal primarily with venereal diseases, but other ailments of seamen will be treated, and it will, in fact, serve as a clearing house for the provision of treatment for tropical diseases, &c. The Liverpool Corporation and the neighbouring Mersey-side sanitary authorities are unanimous in their desire to secure powers to compel sufferers from venereal diseases to seek medical advice and to follow the doctor's instructions. Clauses for the purpose of achieving this object have been inserted in the next Liverpool Corporation Bill, and the text of the clauses is given in Dr. Hope's report. The necessity for the provision of a hostel, where young women suffering from venereal diseases can be housed during the infectious stage, has been recognised for some years, and arrangements have now been made with the Liverpool Diocesan Association to provide such an institution for the accommodation of 15 women. The corporation will pay towards its upkeep. With the approval of the Ministry of Health educational propagandism with regard to these diseases is undertaken by a joint committee, the members of which are appointed by the Mersey-side boroughs—namely, Liverpool and Birkenhead, Bootle and Wallasey.

The Liverpool tuberculosis scheme received an important addition when the corporation took over Highfield Sanatorium from the West Derby board of guardians for a period of two years. Arrangements have now been made for the purchase of the building. At the end of 1923 there were 289 patients in residence. An arc-light equipment has been installed at the Fazakerley Sanatorium, similar to those in use at Copenhagen and Stockholm. The type was decided upon after an inspection of equipment in use on the continent, and the methods prescribed by Dr. Reyn, of the Finsen Institute, Copenhagen, are being observed in their essential details. As yet, only surgical tuberculosis has been treated (with encouraging results), as it is recognised that great caution is necessary in the use of the arc light for pulmonary disease. Sun treatment is being used so far as it is applicable in our climate. During the last 12 months a careful trial has been made of the treatment suggested by Sir Leonard Rogers, the leader of the leprosy campaign, which consists, put briefly, in the injection of certain fatty substances derived from cod-liver and other oils with the object of raising the patient's resistance to the tubercle bacillus. There was a considerable increase in the prevalence of encephalitis lethargica; 111 cases were notified with 36 deaths. During the autumn the type of the disease altered somewhat and signs of cerebral irritation became a noticeable feature. More than half the cases occurred under 20 years of age. Over 30 years of age the liability to contract the disease appears to be small, but the case fatality increases rapidly with advancing age. The disease has been principally prevalent in the winter months. In only about 9 per cent. of the cases was a history of contact with a preceding case elicited. One of the most distressing features has been the alteration of the mental condition of the children affected. This change may develop at once or not until a period of months or years after the primary attack, and not infrequently this mental degeneration occurs after mild attacks. The change in the child is so characteristic as to enable a diagnosis to be made retrospectively, and a number of such cases have been reported by the school medical officers. The present condition of 41 children under 15 attacked with encephalitis lethargica during 1923 shows that as yet only seven are normal. During April and May, 1924, 16 cases of enteric fever (paratyphoid B) occurred in Liverpool and other cases in the vicinity. During the previous three years there have only been eight cases of this disease. The cause of the outbreak remained a mystery as all the usual food sources of infection could be excluded. Dr. Hope thinks that the agent responsible for the spread of infection must be one that is widely used but not heavily infected, and one which is more used by children than adults. He has received information that the disease has been recently prevalent in Bolton, Wigan, and elsewhere.

The position in Liverpool with regard to housing is still "unhappy." The provision of 6000 houses by the corporation has not enabled arrears to be overtaken, still less has it met the needs of the growing population. The large increase in the number of families living in single rooms has resulted in the registration of 537 additional houses let in lodgings. Dr. Hope estimates that Liverpool is at present worse off from the point of view of housing accommodation than at the close of 1914 by rather more than 10,000 houses. Although the proportion of house building has been greater than in other cities, the needs of Liverpool appear to be greater than those of any other city. The 1921 Census showed that there were in Liverpool 11,064 families occupying one room only as compared with 3822 in Manchester. The percentage of families in Liverpool occupying one room only was the highest among the Lancashire towns—namely, 6·4. In Manchester the percentage was 2·3. Dr. Hope refers to communications from the Ministries of Health, Pensions, and Labour with regard to the after-care of tuberculosis recommending that steps should be taken in good time to ascertain that the home conditions of patients about to leave the sanatoriums are satisfactory, and points out how impossible it is to comply with the suggestion, and that these communications from the Ministries merely bring into prominence one of the many evils resulting from house shortage. Several pages of the report are taken up with extracts illustrative of the thousands of piteous and insistent letters received from applicants for houses. Dr. Hope points out that the original undertakings of the housing committee are approaching completion and that an amplified scheme should be embarked upon forthwith. The scheme for the provision of a new abattoir, adequate to the needs of Liverpool, which has been discussed for 20 years, has made progress during the year, and Dr. Hope trusts that there will be no further delay in bringing into operation this eminently desirable reform. The site secured near the existing Stanley cattle market has been cleared ready for the erection of the new buildings.

As the result of the working of the milk clauses a considerable improvement has been noted during later years in the sanitation of the cowsheds outside the city. The tables given in the report do not indicate that this improvement has affected the prevalence of bovine tuberculosis. Thus out of 593 "bulk" samples of country milk 62 were found to be tuberculous. This gives a percentage of 10·5 as compared with a percentage of 7·6 during the last 11 years. Out of 309 "bulk" samples of milk produced in the city during 1923 19 were found to be tuberculous. This gives a percentage of 6·1 to be compared with an average percentage of 7·2 during the last 11 years. Dr. Hope is in full agreement with the increasing demand for education of the public in health matters, and instances the value of institutions like the Liverpool School of Hygiene for the purpose.

Glasgow.

Dr. A. K. Chalmers says that by far the most important sanitary occurrence of the year was the confirmation by the Board of Health of the Cowcaddens improvement scheme. At the end of the year 107 families had been displaced from houses in the northern part of this area: 101 of the dis-housed families were accommodated in houses on Hamilton Hill, 79 in two-apartment houses, and 22 in three-apartment houses at rentals of 6*s.* 6*d.* and 7*s.* 5*d.* respectively, as compared with rentals of 4*s.* 8*d.* and 5*s.* 10*d.* for the houses from which they had moved. Thirteen of the dispossessed tenants came from one-apartment houses rented at 3*s.* 7*d.* New one-apartment houses have not been permitted by the Dean of Guild Court since 1916. The tenants are reported to appreciate the advantages of their new dwellings as compared with their old ones, and to have reacted favourably to the healthier environment. A lady official of the Salvation Army, familiar with both the old and the new conditions, notices an increasing sense of self-respect among the girls as a result of the change. Progress with the improvement scheme will depend upon the rate at which new houses can be supplied. The margin of unoccupied houses was only 325 in the year 1923, and one-half are of five apartments and upwards. The excess of births over deaths is about 10,000 annually, and only 1200 new houses are being built each year. Instead of the shortage becoming reduced it is increasing, and Dr. Chalmers estimates that about 3800 houses are required annually instead of 1200. Rooms in Glasgow are bigger than in England. Dr. Chalmers therefore takes as a basis for overcrowding an excess of three persons to a room, instead of two persons to a room, the usual basis in England. He quotes figures from the Census showing that 14,131 one-roomed houses are occupied by from 4 to 6 persons each, 1643 by 7 to 9 persons each, and 62 by 10 to 12 persons each; and that 19,596 two-roomed houses are occupied by from 7 to 9 persons, 2832 by from 10 to 12, and 117 by more than 12. On the before-mentioned basis overcrowding is found to be present in 39,922 houses, equal to 19 per cent. of the total number of houses containing four rooms and under. It was mentioned that rooms in Glasgow are usually bigger than in England, but Dr. Chalmers draws attention to the fact that there is a tendency to reduce the size of the rooms, and he views this tendency with some apprehension. As regards the effect on health, it has been found that the death-rate from all causes in the one-roomed houses is double that in the four-roomed houses, while the phthisis deaths in the one-roomed houses are three times as numerous as those in the four-roomed houses.

The description of the work of the V.D. centres shows a slight reduction in new cases, but an increase in the indoor treatment and in the number of out-patient attendances. Dr. Chalmers expresses his dissatisfaction with the scheme as at present carried out throughout the country for various reasons. He is not satisfied as to whether the reduction in cases is a result of the work of the clinics or merely a recession from post-war prevalence. Again, only a small number of gonorrhœa cases seek treatment. Thirdly, the number of cases which cease treatment before being cured is large. In Glasgow it is about 45 per cent. Again, we are getting no answer to such questions as possible alterations of the type of infection, the effect of social conditions, or the economic strain of under-paid female labour. Is there a return commensurate with the cost, he asks. For instance, more cases of congenital syphilis were reported from the Glasgow centres in 1923 than in 1922. On the other hand, there is a decline during the last three years in the prevalence of ophthalmia neonatorum, but this decline may be due to the use of silver nitrate solution for the eyes of newly-born children which was made compulsory by the C.M.B., dating from January, 1922. One of Dr. Chalmers's chief points is that the establishment of the centres has encouraged libertines, and he cites the figures of the municipal V.D. centres at Glasgow during a recent year. During this year there were 745 new male cases, 359 of whom were undoubtedly primary cases. In the case of 311 there was a history of a previous attack, of subsequent exposure to infection, and of recurrence of symptoms. In 61 cases this sequence of events had occurred for the third time, in 12 for the fourth time, and in two for more than four times. In other words, more than half the total number of these male patients were habitual libertines. Dr. Chalmers thinks that the treatment of venereal diseases, which was farmed out by local authorities as a matter of emergency, should now be taken in hand by the local authorities directly with a view to the comprehensive study of the whole problem of the distribution of venereal diseases. Towards this end notification by name and address is the first step on the programme, but can only be applied effectively to large areas.

A milk-borne outbreak of scarlet fever occurred in January and February and was traced to the child of a dairy-farmer who was found in the desquamating stage of the disease and who was said to have had a "blush" on the skin, a sore-throat, and swollen cervical glands three weeks earlier. Some 23 cases were traced to the milk. An unusual occurrence is mentioned in the case of three children who were infected with diphtheria by playing with a child who was subsequently found to be suffering from conjunctival diphtheria. Dr. Chalmers says that for many years 80 to 90 per cent. of the city's milk has been pasteurised by the "Flash" method, and that with commendable enterprise distributors are installing plant for the "Holder" process in conformity with the new regulations. The bulk of the milk in Glasgow is 20 to 36 hours old before it reaches the consumer, and in order to ensure satisfactory results and the delivery of a milk of low bacterial count a closer coöperation amongst producers, distributors, and retailers will be necessary. During the year 126 samples of mixed milk were taken at the railway stations and ten of these, or about 8 per cent., were found to contain tubercle bacilli.

An interesting report by the senior smoke inspector, Mr. Colin B. Park, shows that determined efforts are being made to reduce the smoke nuisance. It is stated that the atmosphere of Glasgow has been materially improved during the last 25 years. In 1899 and 1900 the intimations of excess smoke amounted to 17·5 per cent. of the chimneys observed, whereas during 1922 and 1923 the intimations only amounted to 1·7 per cent. In the earlier years, too, five minutes black smoke in the hour was deemed to be excess, whereas during the latter years the limit used was two minutes of black smoke.

MENTAL HOSPITALS SERVICE.

Hertfordshire.

IN the annual report for 1923 of the Hertfordshire County Mental Hospital, St. Albans, a slight increase in the numbers of certified insane in this county is recorded. There is, nevertheless, still surplus accommodation. The recovery rate on direct admissions is 38·5 per cent., and the death-rate 6·11 per cent. Although three deaths occurred from dysentery and six from tuberculosis, there is no record of the degree of prevalence of these diseases in the hospital, or, indeed, any reference to the general state of health of its inmates. There is no record of any visit by a Commissioner of the Board of Control. This report appears to be one in which greater space might with advantage be devoted to the therapeutic aspect of the institution's work.

Carmarthen.

It appears in the annual report of the Joint Counties Mental Hospital at Carmarthen that the population of this hospital is increasing, the male side being overcrowded to the extent of 21 cases. This is the more serious since considerable staff reductions took place last year. There are now only two medical officers, including Dr. John Richards, the superintendent, for over 600 patients, and corresponding reductions in the number of nurses leave the wards at certain times with a "dangerously low staff." Correspondence between the Board of Control and the committee of this hospital has taken place on this question, but there is no indication that any steps are to be taken to carry the recommendations of the Board into effect. Other adverse criticisms appear in the report of he visiting Commissioner. No temperature charts are kept for patients who are ill; tuberculous cases are nursed in the ordinary infirmaries where also some of the new admissions are sent; some 35 cases of diarrhœa have occurred, and no steps have apparently been taken to ascertain whether these are dysenteric. Otherwise the hospital has been free from epidemic disease. The maintenance rate for patients in the three counties (Carmarthen, Cardigan, and Pembroke) is now 19*s*. 3*d*. per week.

Barnwood House Hospital, Gloucester.

In the annual report of Barnwood House Hospital for the Insane, Gloucester, for 1923, may be traced the effects of the small-pox epidemic in that city last year. It is not surprising that a considerable falling-off n the admissions took place; with few exceptions, the entire population of the hospital had to be vaccinated. Last year's report recorded the admission of a large proportion of voluntary boarders, and it is now observed that "there is an increasing demand for voluntary admission, but a considerable number of hose admitted are found to be definitely certifiable." No less than 11 such admissions were eventually certified, and with one exception sent to other institutions on certification. A similar difficulty has been encountered at the Manor House, a separate home for cases not requiring certification, the applicants often being found unsuitable for treatment there, and there is ome prospect of amalgamating this house with the main hospital and accommodating certified cases n it. It may be remembered that a similar fate has recently befallen Millfield, a voluntary home in connexion with the Retreat, York. Such a step can only be taken with the greatest regret, but the difficulties of running such a home, and of filling it with suitable cases, are extreme, and we may yet be orced to the conclusion that the key to the effective treatment of mental disease of whatever kind, whether established or incipient, severe or slight, lies n the reorganisation of the mental hospitals themelves. Several innovations are recorded at Barnwood House. There are now classes of instruction for emale patients in Swedish exercises and art needlework. A laboratory is being equipped for routine pathological work, and the medical superintendent, Dr. A. A. D. Townsend, is asking for the appointment of a regular visiting dentist. It is discouraging that of 27 entrants for the preliminary examination of the Medico-Psychological Association only nine were successful; of two entrants for the final, one passed. It has been observed elsewhere that the only means of persuading nurses and attendants to obtain qualification is to make promotion and increases in salary dependent upon it. Possibly the effect of such an order would be that a sufficient staff could not be maintained.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 25TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 10 (compared with 80 last week); scarlet fever, 2143; diphtheria, 1139; enteric fever, 75; pneumonia, 746; puerperal fever, 41; cerebro-spinal fever, 10; acute poliomyelitis, 27; acute polio-encephalitis, 1; encephalitis lethargica, 46; dysentery, 9; ophthalmia neonatorum, 109. There were no cases of cholera, plague, or typhus fever notified during the week.

We understand that the nine cases of acute polio-encephalitis included in the return for the week ended Oct. 18th, as notified from Liverpool, were cases of encephalitis lethargica.

Deaths.—In the aggregate of great towns, including London, there were 7 deaths from enteric fever, none from small-pox, 12 from scarlet fever, 30 from diphtheria, 14 from measles, 37 from influenza. In London itself the diphtheria deaths fell to 5, and the deaths from infantile diarrhœa numbered 26.

The Services.

ROYAL ARMY MEDICAL COLLEGE.

Maj. J. A. Manifold, R.A.M.C., to be Assistant Professor.

ROYAL ARMY MEDICAL CORPS.

Capt. W. E. Tyndall is granted the temp. rank of Maj. whilst empld. as Dep. Asst. Director of Pathology.

MILITIA.

Capt. M. K. Nelson to be Maj.

TERRITORIAL ARMY.

Lt. J. A. L. Loudon to be Capt.

The King has conferred the Territorial Decoration upon the undermentioned Officers: Majors F. W. B. Young, A. Walker, and G. B. Gill; and Capt. E. B. Keen.

ROYAL AIR FORCE.

Flying Officer J. G. Russell is promoted to the rank of Flight Lt.

MEDICAL CANDIDATES FOR PARLIAMENT.

SUCCESSFUL AND UNSUCCESSFUL.

THE following is a complete list to date of medical men entitled to sit in the new House of Commons. In the constituency of the Scottish Universities, for which one of the candidates, Sir George Berry, is a medical man, the poll will not be declared until Nov. 13th.

Members.	*Constituency.*	*Party.*
Dr. Walter E. Elliot	Glasgow (Kelvingrove)	C.
Dr. F. E. Fremantle	Hertford (St. Albans)	C.
Dr. L. Haden Guest	Southwark, North	Lab.
Sir Henry Jackson	Wandsworth, Central	C.
Dr. E. G. Graham Little	London University	Ind.
Sir Richard Luce	Derby	C.
Dr. Alfred Salter	Bermondsey, West	Lab.
Dr. Drummond Shiels	Edinburgh, East	Lab.
Prof. T. Sinclair	Queen's University, Belfast	C.
Dr. Thos. Watts	Manchester (Withington)	C.
Dr. J. H. Williams	Carmarthen (Llanelly)	Lab.

List of Medical Candidates for Parliament.

A list of medical candidates is here given, showing the individual position at the poll, and the number of votes registered. A dagger sign indicates membership of the last House of Commons, while an asterisk indicates that the candidate contested this or some other seat at the last General Election.

Constituency.	Name.	Position at poll.	Votes registered.

Foreign Decorations.—Dr. Arthur Ferguson MacCallan, C.B.E., formerly Director of Ophthalmic Hospitals, Egyptian Department of Public Health, has been granted His Majesty's Royal licence and authority to wear the Insignia of the Second Class of the Order of the Nile, conferred upon him by the King of Egypt in recognition of valuable services rendered.

GENERAL MEDICAL COUNCIL: ELECTION OF DIRECT REPRESENTATIVES.

England and Wales.

We published last week the election addresses of five candidates for the four vacancies on the Council. Five other nominations have now been sent in and the list is not finally closed as we go to press. The additional candidates are: Dr. Henry Jasper Cardale (London), Dr. Harry Francois Devis (Downend, near Bristol), Dr. Robert Fielding-Ould (London), Dr. Edward Andrew Gregg (London), and Dr. Gordon Reginald Ward (Sevenoaks). We have only received as yet the election address of Dr. Fielding-Ould. which runs as follows:—

Dear Sir (or Madam),—Nominated as a candidate for the approaching election of Direct Representatives in the General Medical Council I have the honour to ask for your support and vote.

The ever-increasing interest and activity of the State in matters connected with Public Health will in the near future, as in the recent past, bring forward many matters of serious professional importance—matters of vital interest to the Profession as a whole, but especially to the General Practitioner.

Until we have before us the Report of the Royal Commission now sitting on National Health Insurance it is impossible to say what changes in medical affairs may result from its deliberations, but it is clear that there has never been a time in the history of Medicine when adequate representations of the General Practitioner on the ruling Council was more necessary. In my deliberate opinion four Direct Representatives in a body numbering 37 cannot be regarded as *adequate* representation.

It is my conviction that increased representation on the Council of the general mass of practitioners would be of the greatest possible advantage to the Profession as a whole, and I believe that, in these progressive days, it is necessary that the powers of the, and influence of the, Council should be increased and stand upon a broader basis so that a body truly representative of the Medical Profession may be gradually evolved.

That any group should nominate and secure the election of all four Direct Representatives is contrary to the best interests of the Profession and to the spirit of the Act of Parliament. The British Medical Association succeeded in doing this at the last Election and is seeking to repeat the manœuvre on this occasion. I submit that Direct Representation must not be regarded as the monopoly of any one organisation, as it is in danger of becoming.

My long connexion with the National Medical Union—the Non-Panel Practitioners Organisation—is a guarantee that the interests of this important section of the Profession will be safeguarded, and in the event of my election your Direct Representatives will no longer be open to the criticism in that they are representatives only of a camarilla.

The knowledge and experience gained in 30 years of public and professional life secure that as your Representative I shall be fully qualified and trained to voice successfully your opinions and advance your ideals. My legal training as a Barrister-at-Law will be an advantage in elucidating the many problems with which the General Medical Council is constantly concerned.

To watch the influences, which often by subterranean methods aim at the socialisation of the Profession and, so far as is possible and desirable, to avert their evil consequences in the interests of the whole mass of the people, shall be my constant and earnest endeavour.

The improvement and reorganisation of Medical Education I have much at heart and I shall, if given the opportunity, do all that is possible to promote and develop improved facilities for post-graduate study. The Medical Education of women shall have my special attention.

The dangers of unqualified practice must be curtailed. I submit that your Representatives should give immediate attention to this matter, and in the event of election it is my intention so to do.

Should you do me the honour of electing me as one of your Direct Representatives, it will be my firm determination to do everything in my power to maintain the efficiency and prestige of the Medical Profession and to fully justify your confidence.

Robert Fielding-Ould, M.A., M.D. Oxf.,
M.R.C.P. Lond.,
Barrister-at-Law, Inner Temple.

9, William-street, Knightsbridge, S.W.,
October 15th, 1924.

Dr. JOHN BROWN, an independent candidate in 1919, who wrote last week that he was not standing, now writes :—

At the request of many of the Blackpool doctors I have consented to be nominated as one of the four to be elected at the forthcoming election. At the election, 1919, there were 15 duly nominated. Only those nominated by organised Medical Associations were elected. My nomination has been signed, and I hope to publish my address in due course in the medical papers. I have no Committee, nor any funds but my own. It is felt that Lancashire ought to have one of the four. The population is about 5,000,000, and there are about 4000 electors. I am a Member of the British Medical Association and my appeal is also to those of the 14,000 who are non-members whose free and independent suffrages I seek. My experience is panel and general practice ; also as Medical Officer of Health from 1877 to 1914 for the Borough of Bacup, Poor-law, Post Office, School M.O., &c., are proofs of my general knowledge.

JOHN BROWN, M.D., D.P.H.

Hornby-road, Blackpool, Nov. 3rd, 1924.

IRELAND.

Dr. LEONARD KIDD, who has been Direct Representative for Ireland since 1906, has addressed the following letter to the registered medical practitioners of Ireland :—

LADIES AND GENTLEMEN,—You are probably aware that owing to the establishment of the Irish Free State the relations of Irish Medical Practitioners to the British Medical Register and to the General Medical Council are in suspense, and that unless the Free State and Imperial Governments agree that the old relations of Irish Medical Practitioners to the British Register and General Medical Council shall be resumed and continued "the relations and responsibilities of the General Council of Medical Education and Registration of the United Kingdom in future will be restricted to Great Britain and Northern Ireland. The Universities and Licensing Bodies and the Medical Practitioners of Southern Ireland will no longer be entitled to representation on the Council. The Medical qualifications granted in the Irish Free State will no longer entitle the holders to be registered in the British Register."

In order to provide further time for consideration of the matter the Dail has introduced a Bill to arrange for the continuance of the old conditions and relations for a year. If the Free State at the end of the year decide to establish their own Medical Register and Council, the Direct Representative elected in November would presumably be in office for one year only (instead of the normal five years), but if on the other hand it is decided to resume the old relations, the election in November would be for the full period of five years.

My term of office as Direct Representative for all Ireland expires on Dec. 31st, 1924. In compliance with the Medical Acts the election of my successor thus rendered necessary must be in November, 1924.

Owing to the expense incurred to the Irish Branch Council, it is desirable there should not be a contested election in November, 1924, and possibly others in November, 1925, for a Representative on the Free State Council, and in Northern Ireland for a Representative on the British General Council.

It has been suggested to me that I should offer myself for re-election in November, 1924, even on the chance that my term of office would be for one year only. This I am prepared to risk, and wish to add that if there is only one other candidate nominated, in order to avoid a contested election, I am prepared to withdraw if a majority of my nominators so desire, but if more than one other candidate is nominated a contest could not be prevented and I shall remain a candidate.

Subject to the above conditions the following have kindly consented to nominate me :—

In Dublin.—Sir John Moore, Sir E. C. Bigger, Dr. J. O'Carroll, Dr. T. Nesbitt, Sir T. Myles, Dr. L. Cassidy, Dr. Seton Pringle, Dr. T. Gordon, Sir A. Chance, Dr. H. Drury, Dr. J. Spears, Dr. E. Magennis, Prof. D. J. Coffey, University College, Prof. A. F. Dixon, Dublin University, Sir Robert Woods, Dr. Walter G. Smith, Dr. H. Bewley.

In Belfast.—Colonel A. Fullerton, C.B., Dr. G. Robb, Dr. W. Caldwell, Dr. H. P. Malcolm, Dr. R. W. Leslie, Colonel T. I. Sinclair, C.B., Dr. H. L. MacKisack, Dr. J. Campbell, Dr. J. A. Craig, Prof. W. J. Wilson.

In the Provinces.—Dr. T. Tate, Downpatrick : Dr. Macbride, Castlebar ; Dr. Warnock, Donegal ; Dr. Mills, Ballinasloe ; Dr. Johnston, Lisburn ; Dr. Thompson, Omagh ; Dr. Meagher, Tullamore ; Dr. Dennis Walshe, Graigue ; Dr. Darling, Lurgan.

Instead of issuing an address which might in present circumstances have the undesired effect of introducing controversial matters, I have decided to refer very briefly to the Constitution and duties of the Council, matters of which many medical practitioners have little knowledge, they and the public often confusing it with the Council of the British Medical Association.

[Here follows a brief sketch of the duties of the General Medical Council in respect of education, registration, discipline, and the British Pharmacopœia concluding : "The Council is neither a Parliament for making professional laws, nor a Union for professional interests. It exists solely for the safeguarding and protection of the public."]

To members of the Poor-law and other Medical Services it may seem disappointing that I make no reference to the disabilities under which they serve, their inadequate salaries, the want of superannuation, the need for an M.O.H. for each county, and so forth. These are all matters that have my entire sympathy, and I can claim to have taken no small part in having them brought under public notice and to have done my best to assist in their redress. They are, however, matters quite outside the functions of the General Council and I have therefore now, as in my former contested elections, refrained from reference to them—indeed to suggest that the Council could mitigate the disabilities complained of would be mere deception. The remedy lies not through the Medical Council but by every practitioner in Ireland joining one or other of the Medical Associations now so badly supported.

L. KIDD, M.D.,
Past President, Irish Medical Association
and of the Ulster Branch B.M.A.

Enniskillen, October, 1924.

ROYAL MEDICAL BENEVOLENT FUND.

AT the last meeting of the committee of this Fund 57 cases were considered and £673 voted to 47 applicants. The following is a summary of some of the new cases relieved :—

Widow, age 45, of M.D. Edin. who practised in Leeds and died from influenza and pneumonia after two days' illness this year. Applicant is left with three boys, ages 11, 6, and 3. Her total income is £140 per annum from investments and £5 per week from two paying guests. She is very anxious about the children's education and asks the Fund to help with school fees for the second boy. A small grant was made and the case handed over to our Guild.

Daughter, age 50, of L.R.C.P. and S. Edin. who practised in Flint and died in 1915. Applicant is asking the Fund to help her, as owing to lack of work and often not having the means to seek work or materials to do fresh work for sale she is handicapped. She is an artist and was employed by a motor firm which unfortunately failed, thus throwing her out of employment. Her rent is 13*s.* 6*d.* per week. From January to April she managed to make £1 per week but since it has only been 10*s.* Voted £10.

Widow, age 61, of F.R.C.P. Edin. who practised in Middlesex and died in August last. The practice was chiefly a panel one and the applicant received £200 for the goodwill, but after paying expenses only £15 is left. An annuity of her late husband's died with him and she has only £26 per annum. Voted £5.

Daughter, age 79, of M.R.C.S. Eng. who practised at Chelmsford and died in 1866. Applicant has cataracts in both eyes and has fractured her left wrist. This case was sent to the Fund by The Gentlefolks Help, who are only able to help temporarily by making her income up to £1 per week. She receives £7 10*s.* from investments and the Old Age Pension. Voted £5.

Widow, age 46, of M.R.C.S. who practised near Sheffield and died in 1913. While her three children are at school the applicant undertakes private nursing, but she finds it difficult to pay for the education of her youngest girl, aged 11, who, up to last term. had her school fees paid by a friend. This help has now ceased, The last 12 months applicant received £130 from friends, £41 from investments, £25 from nursing. Voted £12 10*s.* and referred to our Guild for a supplementary grant.

Daughter, age 79, of M.R.C.S. Eng. who practised in Surrey and died in 1871. Through the failure of a boarding house which applicant had taken she lost all, including the furniture. Only income the Old Age Pension and her rent is 3*s.* per week. Voted £30 in 12 instalments and a special grant of £5.

Daughter, age 47, of M.R.C.S. Eng. who practised in Surrey and died last month. Applicant's late father was in receipt of a Fund annuity of £30. Applicant suffers from ill-health caused by spinal curvature, and weak heart succeeding 2 years St. Vitus's dance. Quite unable to work and dependent on sister who is an artist. They hope to carry on the house and have boarders. Voted £20 in two instalments.

Subscriptions may be sent to the honorary treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

Royal Medical Benevolent Fund Guild.—The offices and workrooms of the Guild have been moved to 58, Great Marlborough-street, London, W. 1, where parcels of clothing, &c., will gladly be received.

THE LEAGUE OF REMEMBRANCE (1914–1919).

To the Editor of The Lancet.

Sir,—On this, the sixth anniversary of the Armistice, it gives us great pleasure to testify to the activities of the League of Remembrance (1914–1919). Having now had several years of experience of the work of the League, we are in a position to form an opinion of its usefulness. It confers practical benefits to all institutions connected with the health of the nation which care to seek its assistance. This opinion is based not only on an inspection of the work carried on at the League of Remembrance, but also on our practical experience from the hospital point of view of its value in the work of the wards. Hospitals, infant welfare centres, and organisations of a similar kind have only to send materials and pattern, and the League makes them up into the finished article required, without making any charge for its services. We have personally inspected the workrooms; the specially equipped department in which the surgical dressings are made receives our warmest commendation, as also do the hygienic and aseptic principles which are exercised throughout the whole establishment. We can, moreover, testify to the promptitude, accuracy, and excellence with which the work is performed. The League of Remembrance, a continuation of the War Hospital Supply Depot movement, is, we believe, the only institution of the kind in the world. It has proved of great service to the hospitals and the number of appeals for help is continuously increasing. These appeals are straining its present resources to the utmost, and we strongly recommend to public inspection and support this organisation, which has taken as an integral part of its business of remembering, the relief of the sick and suffering. All communications should be addressed to Mrs. E. H. Gibson, C.B.E., Honorary General Manager, League of Remembrance (1914–1919), 1, Marlborough Gate, London, W. 2.

We are, Sir, yours faithfully,

William Arbuthnot Lane.

PRURITUS ANI.

To the Editor of The Lancet.

Sir,—Dr. Louis Savatard in his very interesting and practical article on the treatment of this affection rightly insists on the importance of determining, in every case of anal pruritus, its ætiology before starting the treatment. I should like to call attention to a type of pruritus which is not mentioned in Dr. Savatard's paper—namely, pruritus of mycotic origin, which I described[1] some time ago. During the last 12 years I have had the opportunity of examining and investigating 54 cases of pruritus ani, and in 11 of them I have grown cultures from scrapings of the ano-perianal region, using mycological methods of cultivation—*Epidermophyton cruris* Castellani 1905 (*E. inguinale* Sabouraud 1907), in eight cases; *E. rubrum* Castellani 1909, in two cases; and a *Trichophyton* not yet classified in one case.

These fungi apparently remain dormant in the ano-perianal region for a long time, causing severe pruritus, but practically no objective symptoms; though if the region is examined carefully, minute, slightly raised, red, infiltrated patches may not rarely be seen. An eczematous dermatitis due to scratching may also develop, and a secondary streptococcic infection may become engrafted on the mycotic condition. This mycotic type of pruritus ani may be compared with the well-known pruritus interdigitalis pedum of mycotic origin, in which the pruritus is very severe, though objective signs of an epidermophyton infection are often absent. None of my cases presented active symptoms of Dhobie itch (tinea cruris) of the inguinal region, but six gave a history of having suffered from it some years previously; two of the cases were suffering from pruritus interdigitalis pedum and in both cases *E. cruris* was isolated from the scrapings of the skin of the toes.

In my experience pruritus ani of mycotic origin has no tendency to spontaneous cure. The fungus remains in the perianal region indefinitely, practically dormant, but giving rise to severe pruritus, which, however, may stop completely for certain periods of time. As regards treatment I have found that silver nitrate is fairly efficacious (arg. nitr. gr. xv., spir. æther. nitr. ℥i.); but it should be applied with great care. An ointment containing 2 gr. of chrysarobin to the ounce of vaseline is sometimes effective. This, too, should be used with great care. Painting the parts with a strong lotion of potassium permanganate (gr. xxx. to water ℥i.) is useful in certain cases, also an ointment containing salicylic acid and sulphur (gr. xv. of each to one ounce of vaseline). When an eczematous dermatitis due to scratching is present with severe acute symptoms of inflammation, a soothing treatment should be used first, such as lead lotion, to be followed by the antimycotic measures when the acute symptoms have disappeared. In two recent cases I have obtained excellent results by using the Dhobie itch ointment, first introduced by my friend, Dr. W. E. Deeks, medical manager of the United Fruit Company of America. The formula is as follows: Salicylic acid 4 parts, bismuth subn. 10, mercury salicyl. 4, oil of eucalyptus 10, vaseline and lanolin sufficient to make up to 100 parts.

It is interesting to note that Dr. Deeks found long ago that this Dhobie itch ointment had a very beneficial effect in many cases of pruritus ani, although the existence of a mycotic type of pruritus was not known at that time. I am, Sir, yours faithfully,

London, W., Nov. 3rd, 1924. Aldo Castellani.

SPIRITUAL HEALING.

To the Editor of The Lancet.

Sir,—The conclusion of your interesting leader with this title would seem to be that if "cures" occur, then there can be no question but that they are produced by "emotional" rather than "spiritual" factors; that the cases so cured are none other than neuroses, and the average medical man "can by ordinary techniques effect identical cures himself." You support your thesis by bringing forward the supposed cures wrought by Mormonism, Dowieism, &c., and your article would seem to be inspired by the recent Anglican demonstrations of spiritual healing at Bradford. Surely it is somewhat strange to base the conclusion of your article on such facts and neglect the largest religious body in the world, the Catholic Church, which from the very earliest times has claimed that definite cases of true "spiritual healing" do occur.

There is excellent evidence for the cure of cases which cannot possibly be reckoned as functional. Take, for instance, the celebrated case of De Rudder Oostacker in Belgium who was cured on April 7th, 1875, of an ununited fracture of the left leg which had existed for more than eight years; or that of Marie Borel at Lourdes in 1907, in whom six pyostercoral fistulæ existing in the right lumbar region, through which for five months before going to Lourdes the whole contents of the intestinal canal passed, healed there in less than 48 hours. The evidence for these two cases as well as others equally good can be found in the English translation of Dr. Le Bec's book,

---

[1] Brit. Med. Jour., 1923, ii., 1040.

"Medical Proof of the Miraculous," published by Harding and More. About the former, Sir Bertram Windle, M.D., F.R.S., recently wrote: "I am convinced that the evidence is as conclusive as can possibly be obtained in any case where human beings are witnesses, and in another line would hang the most respected man in England for murder." Again, each year some processes of canonisation occur at Rome. For canonisation four miracles have to be proved as having occurred after death at the intercession of the person canonised; these cases are submitted to an exceedingly strenuous medical examination, the best medical expert evidence available being used.

The whole question of miraculous cures rests on the validity of the evidence, but to discuss the matter of spiritual healing and leave out Catholic evidence is surely analogous to playing Hamlet and eliminating the Prince of Denmark.

I am, Sir, yours faithfully,
DOM FRANCIS IZARD, O.S.B., M.R.C.S., L.R.C.P.
Abbaye de St. Benoit, Maredsous par Maredret, Prov. de Namur, Belgique.

*** The points courteously raised by Dom Francis Izard were discussed in a leading article in THE LANCET of 1920, ii., 307, and in a review of the English version of Dr. Le Bec's book in THE LANCET, 1922, ii., 331.—ED. L.

THE DEGREE OF M.D. BRUSSELS.

To the Editor of THE LANCET.

SIR,—I have recently returned to London from Brussels, and have had several interviews with the University authorities, in order to discuss the reopening of the "Scientific" Degree of M.D. Brussels to foreign graduates, with the following result: All candidates, however well qualified, will be required to submit their degrees or diplomas for consideration to the Secretary of the University and be prepared to spend at least one year at the University, attending the lectures, clinics, and practical work before being allowed to enter for the examinations. These are conducted in French, and there are no papers. The standard of the "Scientific" M.D. is exactly the same as the "Legal" M.D. obtainable only after seven years' residence, but it does not carry with it the right to practise in Belgium. Each case will therefore be judged on its own merits. To give an example: if the candidate held the diploma of M.R.C.P. Lond. or F.R.C.S. Eng., he would only be required to put in nine months residence in Brussels, but if he was the holder of an Indian diploma he might have to put in two or even three years residence according to the standard of the diploma he submitted for consideration by the University authorities. The fees for the year are: Courses, 525fr.; examinations, 110fr.; laboratory fees, 250fr. The degree of M.D. Brussels is thus within the reach of any candidate qualified to practise in his own country, who will learn French, and put in nine months residence at the magnificent University which has just been opened in Brussels.

I would be glad to render assistance in negotiating with the University to any candidate who is desirous of entering for the examinations under these new conditions.

I am, Sir, yours faithfully,
ARTHUR HAYDON, M.D. Brussels,
Hon. Secretary, the Brussels Medical Graduates' Association.
10, Sussex-gardens, Talbot-square, Hyde Park, W.2,
Nov. 4th, 1924.

DENTAL DRESSERS.

To the Editor of THE LANCET.

SIR,—Relying on a Board of Education report which four years ago discussed the Dental Acts Committee, I appear to have been led into an under-estimate of the number of dentists. Sir George Newman there stated: "For all practical purposes there are some 3000 practising dentists in England and Wales, distributed unequally and mainly concentrated in towns." It appears that there are now over double that number fully qualified in every respect, and as many again whose qualification is shown by the fact that their names are on the Register.

The number of dentists, however, is one of the relative "trivialities" to which I referred in my previous letter. It has little to do with the dental hygienist as a promising advance in social care from the standpoint of the educational administrator. He seeks what I have called the maximum result in public health at the minimum cost, and is asking whether it is necessary to employ officers who have gone to the cost in money and time of a full training in all the possibilities of disease and disorders of the teeth and their substitutes, and the greater part of whose acquirements will be lost to the community if wholly employed in the routine work of school dentistry.

The suggestion is that the routine, which is at least nine-tenths of hygienic dental instruction and care of school-children, according to the instructions of the dental and medical staff, can be rendered cheap and accessible to all, by training for a short time, and only for the special purpose, these dental nurses or hygienists who can be trusted to do the routine work on their own responsibility and to refer unusual cases to the dentist. Further, it may be asked are there any risks which are numerous or serious enough to negative this work in the form which Dr. Barwise suggests? That is the real topic for discussion. At present it has not been discussed, and administrative action which many, including myself, think entirely unjustified, holds up a great advance. It would be worth while if some of the objectors would set out the grounds of their objection fully and completely.

I am, Sir, yours faithfully,
JAMES KERR.
Mecklenburgh-square, W.C., Nov. 2nd, 1924.

TREATMENT OF HÆMORRHOIDS BY PITCH TAKEN INTERNALLY.

To the Editor of THE LANCET.

SIR,—From Dr. Webber's note on this subject in THE LANCET of August 9th it would appear that the value of this practice is not generally recognised. I became acquainted with the use of pitch for this purpose more than 40 years ago. Since then I have constantly employed this treatment in nearly all such cases that presented themselves to me, and the result has been almost invariably successful and the improvement so rapid that, as a rule, troublesome symptoms have disappeared in a week or ten days. As far as I know, relapses and recurrences have not taken place and very few, if any, have required an operation afterwards. I am accustomed to prescribe pitch—i.e., *Pix liquida* (Stockholm tar) with an equal weight of powdered liquorice in 5-gr. pills, three or more to be taken daily. I find that Meadow's "Prescriber's Companion (1886)" says that capsules of *Pix liquida* are used extensively on the continent for hæmorrhoids and cystitis. This book also gives a pil. picis similar to mine, but it is not clear whether it is made of *Pix burgundica* or *Pix liquida*, and no uses are given. It would be interesting to know whether there is any difference in the action of pitch (as apparently administered to Dr. Webber) and *Pix liquida*. I am told by seafaring men that Stockholm tar is often employed as a local application for piles at sea. Is it too vague a speculation to suppose that the use of pitch and tar for this complaint is of maritime origin? Notwithstanding the tough insides of hardened sailors, the constant use of very coarse food in the protracted voyages of former days must have made piles a very common complaint, and this must have led to the accidental discovery, something after the manner of the Chinaman and roast pig, of a remedy close at hand. I should like to add that I find cold water and glycerine much more useful and pleasant for local application than the standard ung. gallæ c. opio.

I am, Sir, yours faithfully,
F. LUCAS BENHAM, M.D., M.R.C.P.
Semaphore, S. Australia, Sept. 26th, 1924.

Medical News.

University of London.—The second of four lectures on Enzymes will be given by Prof. John Mellanby, M.D. (Professor of Physiology in the University), at St. Thomas's Hospital Medical School, Albert Embankment, S.E. 1, at 4.30 P.M., on Thursday, Nov. 13th. The remaining two will be given on Nov. 20th and 27th respectively.

The Schorstein Memorial Lecture will be delivered by Sir Arthur Keith, F.R.S., on Wednesday, Dec. 17th, at 4.15 P.M., in the Anatomical Theatre of the London Hospital Medical College, Turner-street, Mile End, E. 1. The subject is the Clinical Importance of the Bulbus Cordis. The lecture will be illustrated by lantern slides. Members of the medical profession are invited to attend.

Sir Cuthbert S. Wallace has been elected Dean of the Medical Faculty of the University of London for the period 1924–26.

University College Hospital.—Three lectures on the History of Medicine will be delivered at the Hospital Medical School, Gower-street, W.C. 1, by Dr. Charles Singer on Thursdays, Nov. 20th and 27th, and Dec. 4th, at 4.15 P.M. The subjects are: (1) Recent Light on the Origin of Syphilis; (2) the Beginning of Anatomical Study; (3) the Scientific Work of Robert Koch. The lectures are open to all medical students of the University of London.

University of Bristol.—At a special Final Examination for the degrees of M.B., Ch.B., Part II. (Forensic Medicine and Toxicology only), completing examination, Robert H. Dummett was successful.—At a special Final Examination for the diploma in Dental Surgery the following candidates were successful: William B. Bowrey, William H. Greet, Daniel Griffiths, Cyril H. Hill, and William H. Phillips.

Royal College of Physicians of London.—An ordinary Comitia of the College was held on Oct. 30th, the President, Sir Humphry Rolleston, being in the chair. —The following candidates, having passed the required examination, were admitted as Members of the College: Drs. Stanley Batchelor, Davis E. Bedford, Jyotish Chandra De, William D. Forrest, Malcolm K. Gray, Anis Salama, Kenneth J. L. Scott, and Terence W. Turner.—Licences to practise physic were granted to 245 candidates who had conformed to the by-laws and regulations and passed the necessary examinations. The following are the names and schools of the successful candidates:—

C. H. Ackroyd, Leeds; F. N. Adams, St. Bart.'s; Iris I. G. Adams, St. Mary's; C. Adamson, Cambridge and Durham; B. Adlington, King's Coll.; G. L. Alexander, St. Bart.'s; A. J. Amor and S. M. Anderson, Middlesex; T. F. Anderson, Cambridge and Univ. Coll.; L. V. Angel and H. Aukland, Liverpool; Georgette Bachrach, Univ. Coll.; J. M. Bailey, St. Thomas's; H. C. J. Ball, St. Bart.'s; G. W. Bamber, Cambridge and Univ. Coll.; L. J. Barford, Oxford and Guy's; Alison E. M. Barnaby, Royal Free; C. F. J. Baron, St. Bart.'s.; R. M. Barron, St. Thomas's; S. A. Beards, London; L. F. Beccle, Guy's; A. E. Beith, St. Bart.'s; P. C. Bennison, S. Berman, and E. H. J. Berry, Guy's; A. G. Bewes, St. Thomas's; H. E. Blake, Guy's; R. H. Boggon and A. J. S. L. Boyd, St. Thomas's; W. H. Bradfield and J. H. Broadhead, Guy's; G. C. W. Brown, E. Buchler and G. H. Buncombe, St. Bart.'s; N. F. C. Burgess, Guy's; M. Byala, Liverpool; A. Canard, Cape and Guy's; T. E. Cawthorne, King's Coll.; P. F. Chandler, London; W. T. R. Chapman and F. W. Charman, King's Coll.; K. R. Chaudhri, St. Mary's; W. J. B. Chidlow, Liverpool; Florence C. Churcher, Univ. Coll.; S. Cieman, Toronto and Guy's; T. A. Clarke, Liverpool; E. E. Claxton, St. Bart.'s; I. Cohen, Univ. Coll.; W. R. F. Collis, King's Coll.; W. S. C. Copeman, St. Thomas's; J. W. E. Cory, King's Coll.; A. B. Cowley and B. W. Cross, St. Bart.'s; B. Crosthwaite, Durham; W. I. Daggett, King's Coll.; A. A. Dalby, Guy's; A. F. C. Davey, Manchester; D. Davies, Guy's; D. J. Davies, Middlesex; E. W. P. Davies, Cardiff and Westminster; L. F. Davies, Guy's; Kathleen Davies, Charing Cross; F. M. Deighton, Univ. Coll.; G. W. S. de Jersey, St. Thomas's; P. H. Diemer, St. Bart.'s; J. M. Dobie, St. Thomas's; W. A. Drake and C. S. Drawmer, St. Bart.'s; J. Dreadon, Otago; W. A. D. Drummond, Dundee; G. D. Drury, St. Bart.'s; H. A. Dunlop, Westminster; J. D. Durance, St. Mary's; S. F. Durrans and D. F. Durward, Guy's; H. C. Edmunds, King's Coll.; J. T. R. Edwards, St. Bart.'s; Josephine O. Ellen, Charing Cross; J. B. Ellison, St. George's; Marguerite Elman, St. Mary's; H. G. English, Univ. Coll.; A. J. Enzer, St. Bart.'s; J. A. Evans, Sheffield and Charing Cross; J. P. Evans, St. Mary's; Sarah Evans, Charing Cross; W. Evans, London; W. G. Evans, St. Mary's; N. J. Everard, Sheffield; S. A. M. Fam, King's Coll.; W. J. C. Fenton, F. E. Fox, and D. Frost, London; G. A. Fulton, Liverpool; J. H. Gaddum, Univ. Coll.; H. C. Gage, St. Mary's; J. A. Galletly, Middlesex; J. Gaughan, Liverpool; M. Geaney, Sydney and Middlesex; N. T. Glynn, Liverpool; S. Goldstein, Westminster; Minnie Gosden, London; B. Green, Charing Cross; F. G. Greenwood, St. Bart.'s; Elsie C. Griffin, Madras and Charing Cross; H. F. Griffiths, London; J. I. Griffiths, Univ. Coll.; J. F. Hamber, King's Coll.; A. C. Hampson, Guy's; C. L. Harding, St. Bart.'s; H. E. Hargreaves, Charing Cross; Iris M. Harmer, Univ. Coll.; W. E. Heath, St. Thomas's; Margaret R. Hereford, Royal Free and St. Mary's; W. A. Hervey, St. Bart.'s; A. H. Heyworth, Manchester; F. Hoffstein, Charing Cross; J. G. Hume, St. George's; W. E. Hunter, Manchester; D. S. Huskisson, Guy's; H. V. Ingram, Durham; Adele H. Jacob, Royal Free; H. N. Wignaraja, Ceylon and Middlesex; E. R. P. Williams, Univ. Coll.; H. K. Williams and F. A. Wilson, Guy's; and Ellen Wirtz, Royal Free.

Communications were received from: (1) The Secretary of the Royal College of Surgeons, reporting proceedings of the Council of that College on July 31st and Oct. 9th, 1924. (2) The Director-General of the Medical Department of the Admiralty, dated Oct. 1st, reporting that the Gilbert Blane Medal has been awarded to Surgeon Lieut.-Commander H. B. Padwick, D.S.O., R.N.

Admission of women to the Fellowship: It was resolved for the first time that alterations in By-law No. 194 be made, permitting the admission of women to the Fellowship of the College. This alteration will require to be passed a second time at a subsequent Comitia before it becomes effective.

Dr. W. S. A. Griffith drew attention to a paragraph in the Supplement to the *British Medical Journal* of Oct. 4th, 1924, relating to an instruction by the American Immigration Authorities that persons who desire to emigrate from this country to the United States must be examined by medical practitioners who are members of the British Medical Association. After some discussion, in which Dr. R. A. Bolam took part, it was resolved that the attention of the President of the General Medical Council should be drawn to the injury which the proposed arrangement would inflict on medical practitioners who are not members of the Association. They would be precluded from giving medical certificates even to intending immigrants who were their own patients.

A report was received from Dr. Drewitt, concerning the Chelsea Physic Garden. This was entered on the minutes.

The President announced the award, by the Royal College of Surgeons, of the Jenks Scholarship for 1924 to Mr. A. R. C. Higham.

A report was received from the Committee of Management, dated Oct. 7th, as follows :—

I. The Committee report to the Royal Colleges that the following Institutions have been recognised for the course of instruction for the several special Diplomas :—

1. *For the Diploma in Ophthalmic Medicine and Surgery* :—(*a*) For complete courses, under paragraph V. of the Regulations : The Royal Eye Hospital, Manchester ; St. Paul's Eye Hospital, Old Hall-street, Liverpool ; the Glasgow Eye Infirmary, Berkeley-street, Glasgow. (*b*) For partial courses, under paragraph V. (*a*), (*b*), and (*c*) of the Regulations : The Royal Infirmary, Hull.

2. *For the Diploma in Psychological Medicine* :—(*a*) For resident, or whole-time, appointment for six months, or for clinical instruction for 12 months : The Maudsley Hospital, Denmark-hill, S.E. 5 ; Bloemfontein Mental Hospital, South Africa ; Grahamstown Mental Hospital, South Africa ; Pietermaritzburg Mental Hospital, South Africa ; Pretoria Mental Hospital, South Africa ; Valkenberg Mental Hospital, South Africa.

3. *For the Diploma in Laryngology and Otology* :—(*a*) For complete courses, under paragraph V. of the Regulations : The Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C. 1 ; Hospital for Diseases of the Throat, Golden-square, W. 1 ; Metropolitan Ear, Nose, and Throat Hospital, Fitzroy-square, W. 1 ; Birmingham and Midland Ear and Throat Hospital, Edmund-street, Birmingham ; Liverpool Eye and Ear Infirmary, Myrtle-street, Liverpool ; University of Liverpool Clinical School, Rodney-street, Liverpool ; Manchester Ear Hospital, Grosvenor-square, All Saints, Manchester ; Royal Eye and Ear Hospital, Hallfield-road, Bradford ; Royal Devon and Exeter Hospital, Exeter ; Portsmouth and Southern Counties Eye and Ear Hospital, Pembroke-road, Portsmouth.

II. The Committee report to the Royal Colleges the retirement by rotation from the Committee, under the conditions of paragraph VI., Part I., of the scheme for constituting the Examining Board in England, of Sir William Hale-White and Mr. W. G. Spencer.

Sir William Hale-White was reappointed a Member of the Committee of Management.

Books and other gifts presented to the Library during the past quarter were received and thanks returned to the donors. After some other formal College business the President declared the Comitia closed.

A reception will be held at the College, Pall Mall East, S.W. 1, on Wednesday, Nov. 12th, at 8.30 P.M., to commemorate the 300th anniversary of the birth of Thomas Sydenham. Sir Humphry Rolleston, the President, will deliver a short address.

Society of Apothecaries of London.—At recent examinations the following candidates passed in the subjects indicated :—

Surgery.—J. O. W. Bland, St. George's Hosp. ; E. F. Hottinger, St. Mary's Hosp. ; W. R. S. Jaecques, Ghent ; J. P. McGuire, St. Mary's Hosp. ; A. J. Moody, St. Bart.'s Hosp. ; C. M. Moody, St. Mary's Hosp. ; W. E. Pennington, Liverpool ; and C. J. Rozario, St. Thomas's Hosp.

Medicine.—H. L. Bernstein, Guy's Hosp. ; J. O. W. Bland, St. George's Hosp. ; L. K. Htoe, London Hosp. ; R. D. Jones, Edinburgh and Middlesex Hosp. ; K. Samaan, Cairo and Manchester ; and R. Schofield, Guy's Hosp.

Forensic Medicine.—A. Kaplan, St. Mary's Hosp.

Midwifery.—T. G. L. Davies, St. George's Hosp. ; B. M. Francis, Guy's Hosp. ; L. K. Htoe, London Hosp. ; P. B. P. Mellows, St. Bart.'s Hosp. ; C. M. Moody and A. B. Osbourne, St. Mary's Hosp. ; B. A. Perott, Petrograd ; C. J. Rozario, St. Thomas's Hosp. ; and K. Samaan, Cairo and Manchester.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery : H. L. Bernstein, J. O. W. Bland, L. K. Htoe, W. R. S. Jaecques, R. D. Jones, W. E. Pennington, and R. Schofield.

Royal College of Surgeons of Edinburgh.—The following candidates have passed the Final Dental Examination and have been granted the diploma L.D.S. R.C.S. Edin. :—

Moss M. Bronstein, Andrew Wilson, James L. Jacques, James D. Edminson, Patrick F. D. Delaney, Percy Taylor, Percival F. Hutton, James Hogg, Agnes J. Dalziel, Robert Scott, George S. Robertson, Ernest Lange, John C. Adams, William H. Phimister, Arthur B. Sykes, Walter Ingles, Alfred J. Brown, James M. Coutts, and William L. Graham.

The following candidates passed in the subjects indicated :

Pathology.—Margaret I. MacTaggart, John J. Seaton, and Peter Adair.

Medicine.—Margaret I. MacTaggart and Peter Adair.

Surgery.—Margaret I. MacTaggart, John J. Seaton, and Peter Adair.

West Kent Medico-Chirurgical Society.—A meeting of this society will be held at the Miller General Hospital, Greenwich, S.E. 10, on Friday, Nov. 14th, at 8.45 P.M., when Dr. J. S. Risien Russell will deliver an address on the Value of the Reflexes in Diagnosis.

Medical Society of London.—The second David Lloyd Roberts lecture will be delivered by Dr. Herbert R. Spencer on the Renaissance of Midwifery, illustrated by books and lantern slides, on Wednesday, Nov. 19th, at 5 P.M., at 11, Chandos-street, Cavendish-square, W. 1.

Royal Dental Hospital of London.—The dinner of the past and present students of the hospital will be held at the Trocadero (Empire Rooms), Piccadilly-circus, W., on Saturday, Nov. 22nd, at 6.30 for 7 P.M. Mr. W. Warwick James will preside.

Child-Study Society, London.—A lecture on Women Police Work among Children will be delivered by Commandant Mary Allen under the auspices of this society at the Royal Sanitary Institute, 90, Buckingham Palace-road, S.W. 1, on Nov. 13th, at 6 P.M. Dr. Letitia Fairfield will be in the chair.

Royal Sanitary Institute.—A sessional meeting of the Institute will be held at 90, Buckingham Palace-road, London, S.W. 1, on Tuesday, Nov. 18th, at 6 P.M., when a discussion will take place on the Economic Value of the Healthy Infant and the New Zealand Welfare Work to the State, illustrated by lantern slides, to be opened by Miss J. B. N. Paterson. The chair will be taken by Dr. Louis C. Parkes.

Belfast University Services Club.—On Nov. 11th, at 11 A.M., a wreath, in memory of Queensmen who fell in the late war, will be placed at the base of the War Memorial in the University grounds. One will also be placed at the same time at the Cenotaph in Whitehall, London, S.W. The sixth annual Armistice dinner will take place Thompson's, Belfast, at 7.15 P.M. on Armistice Day.

Harveian Society of London.—The next meeting of this society will be held on Thursday, Nov. 13th, at 8.30 P.M., at Paddington Town-Hall, for a discussion on the Results of Sanatorium Treatment of Tuberculosis, to be opened by Dr. Noel Bardswell.

Royal Statistical Society.—A meeting of this society will be held in the Hall of the Royal Society of Arts, John-street, Adelphi, W.C. 2, on Nov. 18th, at 5.15 P.M., when the President, Mr. G. Udny Yule, F.R.S., will deliver his inaugural address on the Growth of Population and the Factors which Control It.

Medico-Psychological Association.—The next quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland will take place on Thursday, Nov. 20th, at 11, Chandos-street, Cavendish-square, W., under the presidency of Dr. M. J. Nolan, at 2.30 P.M., when a paper will be read by Dr. G. de M. Rudolf, entitled Malarial Treatment of General Paralysis : Some Psychological and Physical Observations.

Refractories Industries (Silicosis) Scheme.—Under the revised scheme to be issued in accordance with the recommendations of the Departmental Committee on Workmen's Compensation for Silicosis, a medical board is to be appointed to undertake the periodic and other medical examinations required under the scheme. This board will have its centre at Sheffield, and will consist of two whole-time medical officers, the senior of whom must have had not less than ten years' practice in the diagnosis of respiratory diseases with special experience of silicosis. Further particulars will be found in our advertisement columns.

Royal Society of Arts.—Among the lectures to be delivered during the coming winter session of this society, at John-street, Adelphi, London, the following are likely to have a particular interest for medical men. Problems of Food with Special Reference to India, by Lieut.-Colonel R. McCarrison, I.M.S., on Dec. 5th, at 4.30 P.M. ; The Trend of Modern Hygiene, by Dr. Andrew Balfour (date to be announced later) ; Cantor Lectures : a course of three lectures on Modern Colour Problems, by Louis C. Martin, D.Sc., on Nov. 24th, Dec. 1st and 8th, at 8 P.M. ; and a course of three lectures on Radiological Research—A History, by V. E. Pullen, Director of the Radiological Research Department, Woolwich, on Jan. 19th and 26th, and Feb. 2nd.

A Scholarship in Hæmatology.—A scholarship of £200 a year tenable for one year and renewable for a second year is being offered by the directors of Virol, Ltd., for the encouragement of British research in hæmatology. In awarding the scholarship regard will be held by the examiners to the following points : (*a*) Original work published or intended for publication by the candidate ; or (*b*) evidence of ability and opportunity to pursue original research in hæmatology ; (*c*) the previous record of the candidate before and after graduation. Selected candidates may be examined orally and practically on their knowledge of hæmatology. The examiners are : Sir William Willcox, Dr. Alfred Piney, and Dr. A. Knyvett Gordon, to the last-named of whom applications should be sent at 10, Bedford-square, London, W.C. 1, before Dec. 1st. Further particulars will be found in our advertisement columns.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Nov. 10th.

WAR: at 5 P.M.
Paper:
Surg.-Commander T. B. Shaw, R.N.: Remarks on the Incidence, Ætiology, and Prevention of Rheumatic Fever in the Royal Navy.

Tuesday, Nov. 11th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
Papers:
Dr. R. D. Lawrence: Cases of Exophthalmic Goitre treated with Insulin.
Dr. G. A. Harrison: The Antagonistic Effect of Insulin and Thyroideum on the Body-weight of Rabbits.

PSYCHIATRY: at 8.30 P.M.
Presidential Address by Dr. C. S. Myers.

Wednesday, Nov. 12th.

SURGERY: SUBSECTION OF PROCTOLOGY: at 5.30 P.M.
Paper:
Mr. Lionel E. C. Norbury: Certain Atonic and Atrophic Conditions of the Cæcum and their Treatment.
Cases and Specimens:
Mr. Hamilton Drummond: (1) Specimen of Sacculitis of Pelvic Colon which caused Death from Portal Pyæmia. (2) Sacculi of Jejunum removed from Patient with Sacculitis of Pelvic Colon. (3) Case of Traumatic Rupture of Rectum into Peritoneal Cavity.
Cases and specimens will also be shown by Mr. Lockhart-Mummery, Mr. Græme Anderson, and others.

Thursday, Nov. 13th.

TROPICAL DISEASES AND PARASITOLOGY: at 5.30 P.M.
Papers:
Dr. Aldo Castellani: Observations on some little-known Diseases of Central America (with illustrations).
Dr. H. B. Day (late Professor of Clinical Medicine, Royal School of Medicine, Cairo): The Relation of Nephritis in Egypt to Intestinal Infection (with illustrations).
Specimens, &c.:
Dr. W. Broughton-Alcock: Appendicitis caused by Oxyuris Vermicularis.
Dr. J. P. Cullen: Two Photographs illustrating Muscular Dystrophy in a Native of the Northern Shan States (Upper Burmah).

NEUROLOGY: at 8.30 P.M.
Paper:
Dr. J. P. Martin: The Syphilitic Types of Progressive Muscular Atrophy.

Friday, Nov. 14th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)
Cases will be shown.

OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)
Cases:
Dr. Rosa Ford: Congenital Ankyloblepharon (two cases).
Mr. A. H. Levy: Acute Macular Disease (two cases).
Papers:
Mr. Ransom Pickard: The Relation between Cavernous Atrophy and Glaucoma.
Dr. Freeland Fergus: Miner's Nystagmus: Its Diagnosis and Origin.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
Monday, Nov. 10th.—8.30 P.M.: Discussion on Encephalitis Lethargica, to be introduced by Dr. E. Farquhar Buzzard, followed by Prof. A. J. Hall, Prof. J. McIntosh, Dr. A. Salusbury MacNalty, and others.

BIOCHEMICAL SOCIETY. (Physiological Department, St. Bartholomew's Hospital.)
Monday, Nov. 10th.—5 P.M., *Communications*:—Dr. G. Thomas: Micro-estimation of Urea in 0·2 c.cm. of Blood. Dr. E. Holmes: Excretion of Salicyluric Acid after Ingestion of Sodium Salicylate by the Human Subject. Dr. R. E. Chapman: Carbohydrate Enzymes of Starch-free Monocotyledons. Dr. E. M. Hume and H. Henderson Smith: Effect of Ultra-violet Irradiation of Environment on Growth and Calcification of Rats fed on Vitamin A-deficient Diet. Dr. G. A. Harrison: Effect of Insulin on Cholesterolæmia. Dr. R. L. Mackenzie Wallis: Observations on Glucose and Lævulose Tolerance Tests.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.
Wednesday, Nov. 12th.—5 P.M., Sir Arthur Keith: Sir Richard Owen as Conservator (Thomas Vicary Lecture).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.
Monday, Nov. 10th, to Saturday, Nov. 15th.—Diseases of Children (Combined Course) at the Paddington Green Hospital, Victoria Hospital, and Children's Clinic. Special Intensive Course. Third week.—St. John's Hospital for Diseases of the Skin, Leicester-square, W.C. Daily demonstrations, pathological demonstrations, and lectures. Second week.—St. Peter's Hospital for Stone, &c., Henrietta-street, W.C. Daily clinical work and special lectures on Urology. Fourth week.—St. Mark's Hospital for Diseases of the Rectum, City-road, E.C. Special Course in Proctology, including lectures, demonstration, and operations. First week.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
Monday, Nov. 10th.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Dr. Saunders: Medical Wards.
Tuesday.—10 A.M., Medical Registrar: Clinical Methods. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.
Wednesday.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients. 4.30 P.M., Dr. Trevor Davies: Gynæcological Demonstration.
Thursday.—11 A.M., Mr. Simson: Gynæcological Ward. 12 noon, Dr. Scott Pinchin: Diseases of the Heart. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.
Friday.—11 A.M., Mr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.
Saturday.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Tuesday, Nov. 11th.—4.30 P.M., Dr. F. G. Crookshank: The Psychology of Common Neuroses.
Friday.—4.30 P.M., Mr. E. Gillespie: *Bacillus Coli* Infection of the Urinary Tract.
Daily: Medical and Surgical Clinics, Clinics in the various Special Departments, Surgical Operations, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Thursday, Nov. 13th.—4 P.M., Dr. Theodore Thompson: Acute Infections of the Nervous System in Children.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
Tuesday, Nov. 11th.—5 P.M., Dr. Knowsley Sibley: Eruptions due to Physical Causes.
Thursday.—5 P.M., Dr. H. MacCormac: Diseases due to Animal Parasites.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
Monday, Nov. 10th.—(At the Children's Hospital.) Dr. Johnson: Tubercular Meningitis.
Tuesday.—(At the Southern Hospital.) Dr. Johnson: Neuritis.
Wednesday.—(At the Northern Hospital.) Mr. McMurray: Deformities of the Feet.
Friday.—(At the Royal Infirmary.) Dr. Wallace Jones: Heart Cases.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES. (At 3.30 P.M.)
Tuesday, Nov. 11th.—(At the Jessop Hospital.) Mr. King: The Treatment of Dysmenorrhœa.
Friday.—(At the Royal Hospital.) Dr. Naish: Points in the Diagnosis and Prognosis of Cretinism.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
Tuesday, Nov. 11th.—4.15 P.M., Dr. E. M. Brockbank: Heart and Aorta Strain.
Friday.—4.15 P.M., Prof. J. S. B. Stopford: The Motor Pathway.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.
Wednesday, Nov. 12th.—3.15 P.M., at the Town Club, Swindon, Dr. A. J. Wright: Tonsils and Adenoids and Ear Discharges.

CHADWICK PUBLIC LECTURES.
Monday, Nov. 10th.—8 P.M. (in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole-street, W.), Mr. Mark Hovell: The True Significance of the Rat Menace and how it may be Minimised.

ROYAL INSTITUTE OF PUBLIC HEALTH, Russell-square, W.C.
(Course of Lectures on the Health of the Commonwealth.)
Wednesday, Nov. 12th.—4 P.M., Colonel Sir Leonard Rogers; Leprosy as an Imperial Problem.

THE PEOPLE'S LEAGUE OF HEALTH. Course of Lectures on the Mind and What We Ought to Know About It.
(At the Medical Society of London, 11, Chandos-street, W.)
Monday, Nov. 10th.—6 P.M., Sir Maurice Craig: Habit and Adaptation.

Appointments.

HOGAN, J. E., L.D.S. Irel., has been appointed Lecturer in Dental Surgery and Pathology in the School of Physic, Dublin University.

HOWELL, B. WHITCHURCH, F.R.C.S. Eng., Surgeon to Brookfield Orthopædic Hospital.

ROBERTS, W. M., M.B., Ch.B. Manch., Assistant Lecturer in Chemical Pathology, University of Manchester.

Certifying Surgeons under the Factory and Workshop Acts: ROBERTSON, W., Westerham (Kent); WINDEMER, D. A., M.R.C.S., L.R.C.P. Lond., Mevagissey (Cornwall).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Mental Hospital.—Third Asst. P. £250.
Belfast, Forster Green Hospital for Consumption, &c., Fortbeda.—Med. Sup. £600.
Birmingham, Queen's Hospital.—P. to Out-patients.
Bolton County Borough.—Asst. M.O.H. and Sch. M.O. £600.
Bristol General Hospital.—Hon. Reg. to Throat and Nose Dept.
Cambridge, Addenbrooke's Hospital.—H.S. at rate of £130.
Cape Town University.—Wernher Beit Chair of Pathology.
Chailey, Sussex, Heritage Craft Schools.—H.S. for Orthopædic Surg. Dept. £200.
Chester Royal Infirmary.—Hon. Asst. Anæsthetists.
Edinburgh Royal Mental Hospital.—Res. Asst. P. £350.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—H.P. Two H.S.'s and Obstet. Asst. at rate of £50 each.
Evelina Hospital for Children, Southwark, S.E.—H.S. at rate of £120.
Kensington, Fulham and Chelsea General Hospital, Richmond-road, Earl's Court, S.W.—Sen. and Jun. Res. M.O.'s for six months at rate of £100 and £75 respectively.
Manchester, St. Mary's Hospitals.—Three H.S.'s for seven months at rate of £50.
Metropolitan Asylums Board Mental Hospitals Service.—Two Jun. Asst. M.O.'s. Each £500.
Middlesbrough County Borough.—Asst. M.O..H £450.
Nottinghamshire County.—M.O.H. £1200.
Rousay and Egilshay Parish, Orkney.—R.M.O. £400.
Royal Naval Medical Service.—Surg. Lieuts. 25*s.* per day.
Ruthin Castle, Duff House, North Wales.—Asst. P. £700.
St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—Third Anæsthetist. £25.
Salford Royal Hospital.—Res. Surg. O. £200.
Sheffield, Workmen's Compensation (Silicosis Acts).—Two M.O.'s. Sen. £900. Jun. £700.
Virol Scholarship in Hæmatology. £200.
West London Hospital, Hammersmith-road, W.—Surg. for Dis. of Women. Dermatologist. Also Hon. Medical Radiologist.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.
York County Hospital.—H.P. £150.

The Chief Inspector of Factories, Home Office, London, S.W. announces a vacant appointment at Cinderford, Gloucester.

Births, Marriages, and Deaths.

BIRTHS.

HORTON.—On Oct. 28th, to Dr. and Mrs. R. L. Horton, of "Morven," Westerhall-road, Weymouth—a daughter.

PARGETER.—On Oct. 27th, at Stamford Lodge, Sevenoaks, the wife of Henry Arthur Aidan Pargeter, M.A., M.B. Camb., of Dunstable, of a daughter.

PRATT.—On Oct. 27th, at the Haylands, Chigwell, Essex, to the wife of Dr. John Henry Pratt, of a son.

SOUTAR.—On Oct. 29th, at "Ardlea," Douglas, Isle of Man, the wife of Alan K. Soutar, M.R.C.S., D.P.H., of a daughter.

MARRIAGES.

LANE—DA COSTA.—On Oct. 28th, at St. Mark's North Audley-street, Gordon Lane, M.D., of Harley-street, W., to Mabel da Costa, of Green-street, W.

DEATHS.

GRAY.—On Nov. 3rd, after pneumonia, at North Holt, Hythe, Kent, Colonel William Lewis Gray, C.M.G., A.M.S. (retired), aged 60.

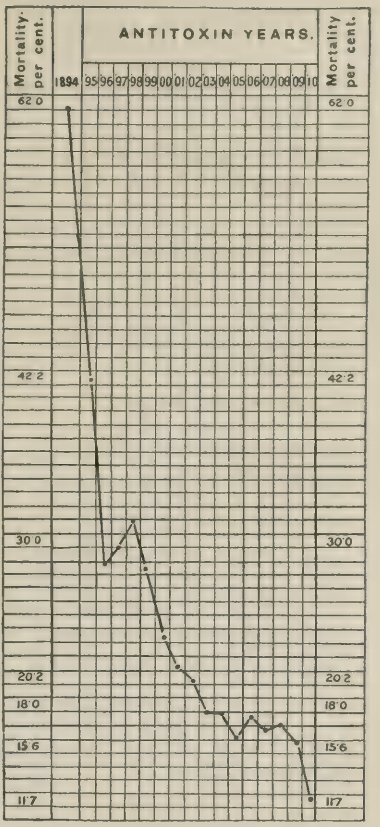
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOBEL PRIZE IN MEDICINE.—This prize for 1924 has been awarded to Prof. William Einthoven, Professor of Physiology in the University of Leyden.

Notes, Comments, and Abstracts.

DIPHTHERIA ANTITOXIN AND LARYNGEAL DIPHTHERIA.

IN 1908, under the presidency of Lord Cromer, there was founded the Research Defence Society, whose object is to make generally known the value and the necessity of experiments on animals; the restrictions imposed on them by the Act of 1876; and the great saving of human and animal lives already obtained by means of such experiments. Every quarter this Society publishes a little journal entitled *The Fight against Disease* (Macmillan, 6*d.*). It contains notes on current experimental work, comments on questions arising in connexion with the administration of the Acts safeguarding vivisection, and records of advances in medicine achieved by animal experiments. The current number includes also a series of three "old stories retold," in which the fascinating tales of the discovery of the lacteals, of Sir Charles Bell's experiments on the nervous system, and of Claude Bernard's early work on the vasomotor system are recalled. Those who are familiar with this journal will recognise the chart, here reproduced, which appears on the back cover of every issue. It records the arresting decrease of the mortality from laryngeal diphtheria following on the introduction in November, 1894, of diphtheria antitoxin into the routine treatment of patients in the hospitals of the Metropolitan Asylums Board.



The chart, which refers only to cases of laryngeal diphtheria and does not include any slight or trivial cases, shows that the average mortality among cases of laryngeal diphtheria came down from 62 per cent. to 11·7 per cent. in sixteen years. The average mortality among tracheotomy cases came down from 70 per cent. to 20 per cent. in the same period. Now although the extensive application of the bacteriological test for diphtheria, coming as it did shortly before the use of antitoxin, no doubt resulted in a somewhat larger number of mild faucial and nasal cases of diphtheria being recognised and sent into hospital, the same explanation does not hold good for the laryngeal cases. Laryngeal obstruction is now just as much an immediate menace to life, and the call for operative relief equally insistent, as it was before the discovery of antitoxin. The only difference has been in respect of treatment. All cases of laryngeal obstruction have been treated with full doses of antitoxin immediately on coming into hospital. The effect of this has been that a certain number, chiefly those in the earlier stage of the disease, or those in which the obstruction has not progressed to the same degree, have not required tracheotomy at all, the obstruction having been relieved as the result of the early administration of serum. This fact, although without influence on the mortality of the wider group of laryngeal attacks, must have the effect of prejudicing adversely the mortality of the tracheotomy cases owing to the exclusion from the series of a certain proportion of the milder and less urgent cases. Had this not been the case, the lowering of mortality in the tracheotomy group, as shown by the statistics, would be even greater.

THE STORY OF A DUBLIN HOSPITAL.

AT the beginning of the eighteenth century there was not a single hospital in Dublin for the reception of sick civilians, although there was some scanty provision for sick soldiers. In 1699 "certain of the Commons" petitioned the Dublin Corporation a piece of ground, according to an annexed description, might be appropriated for the building of a hospital. The corporation granted the petition, but nothing further seems to have been done, and in addition, though the promoters approached the College of Physicians for a medical staff, again nothing was done, even though the President and Fellows on St. Luke's day, 1699, resolved "that att next meeting of ye Colledge of Physicians ye attending of a Hospital to be founded by ye Citty of Dublin for ye sick, be considered." So matters went on until 1718, when six Dublin surgeons opened a house in Cook-street at their own expense for the treatment of patients needing surgical aid. This hospital flourished from the start, and eventually became the present Jervis-street Hospital. In 1720 was founded Dr. Steevens' Hospital, and the history of this institution forms the subject of an unusually interesting book by Dr. T. P. C. Kirkpatrick.[1]

Richard Steevens was the son of John Steevens, who was probably curate in charge of Cherril, a donative of Calne in Wilts. John Steevens resigned his charge and fled to Ireland, on account, it is said, of differences with Cromwell concerning his late Majesty Charles I. This occurred about 1654, and in 1664 we find him rector of St. Mary's, Athlone. He had two children, twins, Richard and Grizel, and Richard, born circa 1653, was educated at the Latin School of Athlone, entered Trinity College, Dublin, in 1670, graduated B.A. in 1675, and commenced master in 1678. He is said to have taken deacon's orders, intending to follow his father's footsteps, but after his father's death in 1682 he changed his mind and began to study medicine, commencing doctor in 1687. Despite the disturbed times Steevens prospered in his profession, and acquired estates to the amount of some 3000 acres. He died in 1710, bequeathing most of his property to trustees to be used after the death of his sister Grizel: "To build or cause to be built or otherwise provide one proper place within the City of Dublin for an hospital for maintaining and curing from time to time such sick and wounded persons whose distempers and wounds are curable." Grizel Steevens, however, who, as was the custom of the time, bore the courtesy title of Madame Steevens, was not disposed to wait until her death for the fulfilment of the charitable desires of her brother. After a short struggle with the Court of Chancery and a fruitless application to the Government for help in 1716, with the consent of the trustees, she decided to give such a sum of money from her private income as would suffice for the building to be started and at the same time promised further annual gifts. Progress was slow, and the building was not opened for the reception of patients until March, 1732–33. Many of the bills for the furnishing of the house have been preserved and form interesting reading to-day. For instance, 40 bedsteads of deal cost 25*s.* each and 50 pewter chamber.pots cost £5 4*s.*, while two dozen "Ocamy spoons" cost 10*s.* These bills are dated 1729. By 1737 prices had risen, for a bill of that date shows that 11 pewter chamber-pots cost £1 7*s.* 6*d.*, but, on the other hand, "ten alkaney spoons" only cost 5*s.* The expressions "Ocamy" and "alkaney" are both obviously corruptions of "alchemy," a term which was applied to a particular kind of fine brass or bronze. Thus a marginal note in the Geneva New Testament of 1577 to the passage from Revelation, "his feet like fine brass" gives "*or* alkumyne." Good Madame Steevens died on March 18th, 1746–47, having lived in the hospital since a little before it was opened for patients. She was a masterful lady, and in 1735 ordered the dismissal of Owen Lewis, the resident surgeon, for what offence is not known, but this is the only time that she interfered in the internal affairs of the hospital. At her death the whole of her property, save for a few trifling legacies, passed by her will to the governors of the hospital. One of Steevens' trustees and an untiring worker for the hospital, which, however, he did not live to see opened, was Thomas Proby, appointed Chirurgeon-General in Ireland in 1699. He gained great renown in Dublin for having removed a bodkin from the bladder of a girl named Dorcas Blake, who said that she had swallowed it. A report of the case was submitted to the Royal Society by Dr. Thomas Molyneux, on referring to which we find that she is said to have swallowed the bodkin, which was made of ivory, on Jan. 5th, 1694. By next evening she felt a pricking pain near her right groin, and on Jan. 7th a midwife who "searched" her felt the end of the bodkin but thought "it was in a gut." On Jan. 8th Proby was called in and felt the bodkin per vaginam. Some days later he tried to extract it through the urethra, but could not. Nine weeks after the "swallowing" he extracted it by a suprapubic cystotomy, and the report states "there was but half the *Bodkin* in the *Bladder* . . . the other half was out of the *Bladder* in the *Pelvis* the point resting upon the *Ischium.*" As Proby felt the bodkin in the bladder three days after the alleged swallowing, and despite Dorcas Blake's sworn oath before the Lord Mayor on June 10th, 1695, that she did swallow it, there seems a reasonable suspicion that she was romancing.

So the record of the hospital continues with interesting biographical details about the staff, some of whose names are household words, such as Colles, Croker King, about whom were written the lines so eminently practical, if not poetical:—

> "The fractured Skull to Samuel Croker King,
> The broken Limb, Wounds and Luxations bring;
> There's no Disaster but he can set right,
> With Splints, Trepan and Bandage not too tight."

Among the physicians and obstetricians Sir H. Marsh, H. J. C. Tweedy, E. H. Tweedy, and Henry Jellett, both the two latter being Masters of the Rotunda, find a place. Dr. Kirkpatrick has provided his readers with an excellent list of the officials connected with the hospital from its inception, illustrated by short biographical notes. There is an admirable index, and finally he slays the extraordinary myth which somehow gained currency that Madame Steevens was the original of the Pig-Faced Lady! Altogether the book is a model of what a hospital history should be.

PRESENTATION TO A MEDICAL MAN.

Dr. F. M. Blumer was presented on Oct. 17th by members of the general committee of the Staffordshire General Infirmary with an illuminated address to mark his 38 years' valuable services to the institution. The address, which was embossed on vellum and bound in morocco, stated among other things that "Your membership of the honorary staff of the infirmary is a record of singleness of purpose, of work well performed," and expressed the appreciation of the committee for Dr. Blumer's decision, at the committee's request, "to continue for a further period as an active member of the medical staff." The presentation was made by Major J. C. G. McFerran, chairman of the board of management, and there was a large gathering of Dr. Blumer's friends and colleagues.

MIDDLESEX HOSPITAL.

THE War Memorial of the borough of Marylebone took the form of the endowment of six beds in the Middlesex Hospital. A sum of money being left over this has been augmented, and on Oct. 27th another bed in the Broderip Ward was opened by Prince Arthur of Connaught, chairman of the hospital, who was accompanied by the Princess. His Royal Highness also unveiled a tablet recording the endowment.

DAIRY-WORKERS AND TUBERCULOSIS.

THE Minister of Health has issued a draft of new Regulations (Public Health (Prevention of Tuberculosis) Regulations 1924) to be made for the purpose of preventing infection from the employment in and about farms, dairies, and milkshops of persons suffering from pulmonary tuberculosis. Under these regulations (*a*) a medical officer of health may report to a local authority that a person employed in connexion with the handling of milk is suffering from pulmonary tuberculosis, and (*b*) on receiving any such report the local authority may by notice in writing signed by the clerk or the medical officer of health require such person to discontinue his employment or occupation on or before the date specified in the notice, such date being not less than seven days after the service of the notice. An appeal against the requirement of the local authority may be made to a court of summary jurisdiction within 14 days from the service of the notice.

ROYAL NORTHERN HOSPITAL, LONDON.

ON Oct. 30th, Princess Louise, Duchess of Argyll, President of the Ladies' Association, opened the new nurses' home at the Royal Northern Hospital, Holloway-road, London, N. Lord Northampton, who, with other friends and officials, received the Princess, referred to the fact that the King was Patron and the Prince of Wales President of the hospital, and said that the new home had been made possible through the help received from King Edward's Hospital Fund for London, the British Red Cross Society, the Ladies' Association of the Royal Northern Hospital, and many generous donors. The cost of the new building, including the site, was £33,900, of which £5900 was still needed.

ANY friend of the late Prof. S. G. Shattock who would care for a copy of the portrait issued with the last number of the *Journal of Pathology and Bacteriology* can have one on application to the Editor, 17, Loom-lane, Radlett.

[1] The History of Dr. Steevens' Hospital, Dublin, 1720–1920. By T. Percy C. Kirkpatrick, M.D., M.R.I.A., Fellow and Registrar of the Royal College of Physicians of Ireland. Dublin: At the University Press. 1924. Pp. 397.

An Address
ON THE
PROGRESS OF PATHOLOGY.

elivered at the Opening of the New Pathological Institute at the University of McGill, Montreal, on Oct. 6th, 1924,

BY A. E. BOYCOTT, M.A., D.M., F.R.S.,

RAHAM PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF LONDON; DIRECTOR OF PATHOLOGY IN UNIVERSITY COLLEGE HOSPITAL AND MEDICAL SCHOOL.

MAY I begin by thanking the University very eartily for giving me the chance of taking part in his ceremony. It gives me the greatest pleasure o be here, and I take it as an unexpected compliment o English pathology that you have asked me; it elps us to know that the common opinion that nglish pathology does not count for very much is ot universally shared. Speaking on behalf of my olleagues, I bring you our best congratulations on chieving this splendid addition to your resources nd our best wishes for the future. We feel, I hink, that we have a special kinship with McGill athology. We both enjoyed the stimulus of Osler, ou at the beginning and we at the end of his career; dami has always been with us more or less, in person r in his books; Miss Maude Abbott has tried to teach any of us how to classify museum specimens, o that we have always had a good deal to do ith you.

The history of academic pathology is brief. Your irst professor was appointed in 1892 and still lives n the world of administration to which he has been alled, and in thinking and talking of pathology t is always well to remember what a young subject t is—still in the exuberant and rather disorderly eriod of adolescence. You are now enjoying your econd professor, and his career has culminated and tarted out on a fresh pilgrimage at a higher level by he provision of this noble institute. You have seen, r will see, for yourselves what a place it is; I need not well on that. I do not set so very much store on uildings and fitments myself—the people who use hem matter much more—but you do want room and ight and plenty of gas, water, and electricity, and t is evident that this new institute is admirably dapted for its purpose. I would rather emphasise ts origin which has, I think, more to teach us. It has een erected by the patriotism of the citizens of ontreal and the loyalty of the alumni of the Univer-ity under the encouragement and stimulation of the ockefeller Foundation, and I do not think I am going oo far when I suggest that this institute would not ave been attained, at any rate in these years, without he aid of that remarkable corporation. The Rocke-eller Foundation is charged to administer its funds "for the good of mankind throughout the world"; t has chosen medical education as its special field, nd there are now schools all over the world from China o Peru which are indebted to the wise generosity of r. Vincent and his colleagues. Has there ever been a ore ample and beneficent example of that inter-ationalism which the world so much needs? We re, I suppose, agreed that the whole ethic of a good ife is summed up in that simple direction "Bear ye ne another's burdens." It is simple enough, but it is ard to do—all those simple rules which Jesus gave s are hard to do, are they not? But I think the ockefeller Foundation has been and is making a retty good attempt. What burden of theirs you re bearing in return I do not know unless it is the urden of some of their liquor.

THE DEVELOPMENT OF PATHOLOGY.

Why is it that we welcome this building? What is athology about that it is worth study? Pathology as come to be such a hodge-podge of interests and ctivities that a definition is difficult. But, roughly peaking, it deals with the causes of injuries to live organisms, with their effects on the body, and with what the body does to try to put things straight. In other words, it is, in its application to man, the study of disease apart from diagnosis and treatment. It began everywhere I think in morbid anatomy, in the investigation of the changes found in the body after death. And in this it still finds its fundamental basis. Though modern biologists sometimes seem to think the contrary, form has still to be taken into account along with function, and if alterations in structure are not now the end as well as the beginning of inquiry the quaint notion that morbid anatomy is played out comes only from those who are ignorant of what the anatomist has to say. And because those who pursued this work were the only people in immediate contact with medicine and surgery who had a liking for, and any skill in, laboratory methods of investigation, it has extended very widely into any laboratory work in relation to sick people. The result is that the content of pathology is singularly various. It is like a Woolworth's window—some of it is worth having at the price and some of it isn't, some of it ought to be there and some of it ought not. Let me illustrate what I mean by two examples taken from topics which have in recent years occupied a considerable share of the printed literature of the subject.

The Wassermann Reaction.

The Wassermann reaction for the diagnosis of syphilis by the examination of the blood was discovered about 15 years ago. It was found out by the logical application of established principles. But it very soon appeared that it had in fact nothing to do with those principles at all; it was an empirical trick, and to this day its rationale remains unexplained and it is a phenomenon which is unrelated to anything else. But it is a first-rate method of diagnosing a disease which has been a stumbling-block in clinical medicine and surgery since Erasmus deplored the evil influence of its growing prevalence on the development of culture in Europe in the sixteenth century. Except in its early stages diagnosis was often simply speculative, and the real prevalence of the disease and its real importance provided an unrivalled field for the guess-work to which we doctors have been almost as prone as the propagandists. The Wassermann reaction has altered all that. We now know who has syphilis and who hasn't; we know that general paralysis and tabes are syphilis; we know that it is a serious disease, but nothing like so serious as tuberculosis, or cancer, or bacterial infections of the heart. All of which you will see is diagnosis—in other words, medicine. To pathology the discovery has contributed practically nothing; it leads nowhere, it illuminates nothing else. It is one of the items in what is called pathology which ought not to be there until it has earned its place in the scheme of rational and related knowledge.

The d'Herelle Phenomenon.

Contrast this with the phenomena recently discovered by d'Herelle and since discussed by him and others in hundreds, I expect thousands, of papers. d'Herelle found that under certain circumstances something appeared in cultures of bacteria which killed and dissolved them. I need not go into the rather technical details; the essence is that this something is associated in an intimate way with the bodies of the bacteria, that it can multiply, and that it is too small to see. Of the facts, two opposed explanations have been put forward. d'Herelle himself holds that the something is a living parasite of the bacillus and thinks that he has found out an important method of circumventing their objectionable activities. Others think that the something is not alive but is a dead ferment. I know of no crucial test which could be applied to settle the point at issue. If it is alive it certainly differs from any other known live thing; if it is dead, it equally certainly differs from any other known dead thing. When serious and skilful investigators have a difference of opinion of this kind, it may always be assumed that the dilemma which they are propounding to one another is not a real one, or that their antagonistic interpretations do not exhaust the possibilities. So it evidently is in this case. Is it alive or dead ? is not the final question, for the something is plainly half alive or half dead whichever way you like to phrase it, and this work has revealed to us the connecting link between live and dead matter which almost everyone has assumed to exist, and which everyone is strangely loth to recognise when it is before them. We now see the whole world displayed in one continuous series from the atom to the elephant. I need not dilate on what a discovery like that means. True, it is of no apparent importance in the treatment of dysentery as d'Herelle hoped, it has no obvious connexion with clinical medicine and surgery. It just helps us to make a substantial step in understanding the world. Is the Wassermann reaction or the bacteriophage the more worth our attention ? The Wassermann test does much for our bodies, it may do a little for our minds when we tot up statistics, it leaves our souls where they were. The bacteriophage knits up some of the greatest adventures of the human mind, it brings together people so diverse as Béchamp and Rutherford, and for my own part I feel the better for it.

Such are two examples of the varied topics of which "pathology" has come to consist. Of its practical utility there is no doubt; some of you may have heard, and more will have read, the statement which the President of the British Association made this year at Toronto of the wonderful progress of recent years. In the dead-house, in parasitology, in nutrition, in chemical pathology, in experimental work, progress has been prodigious along practical lines. In the everyday work of any respectable hospital the methods of pathology take on an ever-increasing importance—parenthetically I may be allowed to suggest sometimes too much; as every pathologist knows there is singular readiness on the part of some of those whose business is diagnosis and treatment to desert the difficulties of the wards for the far easier problems which we make up in laboratories; that, however, is not my business. I remember as a medical student seeing as much of the work of Dr. Jenner's pioneer clinical laboratory in London at St. Thomas's Hospital as a rather autocratic director would allow, and it is interesting to compare the scope of what was done then with what is now commonplace in meaner institutions and under far meaner inspiration. Useful then pathology is. But it is not on that account that we think pathology is worth studying, and welcome so heartily this new encouragement of its pursuit.

THE REASONS FOR STUDYING PATHOLOGY

Dean Gaisford, of Christ Church, once said, about a hundred years ago, that there were three reasons why you should know Greek. In the first place, he said, it enables you to read the words of Jesus in the original; in the second place it allows you to have a hearty contempt of those who are not acquainted with the language; and in the third place it leads to positions of emolument in the Church. Our immediate comments are obvious, and we should naturally say of his first reason that it is untrue, of his second that it is hardly charitable, and of his third—well, the less said about it the better. But at bottom I am not at all sure that the Dean was not putting forward, in a curious way it is true, a very real apology for the study of a subject which has done so much for our right development during the past 400 years. The world 100 years ago was quite a different place from what it is now, and he knew that ample means helped towards the freedom which is wanted for mental and spiritual progress: he realised that this culture admits a man to an intellectual aristocracy which knows itself to have inward resources from which those without Greek are excluded; he wanted to say that if a thing is to be rightly apprehended and in the fullest way you must get down to the root of it, you must read it in the original. This is the real apology for Greek, and it is the real apology for pathology too. We want to study pathology because of our insatiable curiosity to understand things, and because we know that the satisfaction of that curiosity helps us along the world's search for goodness, truth, and beauty. In other words, we want to realise in pathology the ideal which is the basis and impregnable rock of our universities. I am almost ashamed to deliver myself of such platitudes before an assembly for the most part composed, if I may judge from your gay clothes, of university doctors. But things happen nowadays and things are said which seem to make it necessary to state our ideals occasionally in black and white and to remind ourselves for comfort that our rock is, in fact, impregnable. Knowledge is extolled because it is useful; we are told that universities should be run on business lines, that their main purpose is the passing of undergraduates through courses of instruction. People are ashamed to say that they are interested in Greek grammar or the anatomy of crustacea or the necroses of the liver for no other reason than that God has put it into their minds so to be; they must fain produce excuses about political anthropology or inshore fisheries or medicine. Only the other day Prof. A. V. Hill was making excuses to the Royal College of Physicians of London for the study of physiology for its own sake—a sign of the times on which I can make no adequate comment.

I judge, therefore, that the time has now arrived when pathology must recognise that it is a science which can and ought to stand on its own feet and pursue its own end, which is the study of pathology, not the study of medicine and surgery. That it is able to do this and that it can be so studied its achievements have, I think, amply demonstrated. Arising from medicine and having been brought up with that humane kindliness which characterises our profession, it is time it started out on its own; it needs to go to its secondary school and not to have its education stopped at 14 to do chores to help out the family budget as a half-timer. If by one of your miracles of inhibitory legislation you prohibited medicine and surgery to-morrow, pathology would still go on; it is old enough for that now, and I sometimes think it might be none the worse for a holiday right away from its parents.

THE PRESENT STATE OF BACTERIOLOGY.

It is, I believe, only by a recognition that this is the present situation—more or less—that further progress is possible. And surely fundamental progress has been slow enough in recent times. Consider, for example, the present state of bacteriology. The study of it began intensively about 40 years ago; it started technologically and for long was almost purely medical in character and application. Lately other branches—soil, leather, and what not—have grown big, but they are technological too. What is the result ? Its technological progress has been prodigious; our knowledge has not only completely revolutionised medicine and hygiene but has come to be an integral part of the daily life of the general population. Indeed, if I want to explain to some curious laymen what my pre-occupation is, "bacteria and so on" saves trouble and will convey something pretty definite; everybody "knows about bacteria." But bacteriology is now sterile; no discovery of first-rate importance has been made for many years, and we are constantly being brought to a standstill for want of knowledge of how bacteria live and move and have their being—knowledge of a sort which may be called botanical. We do not even know how bacteria multiply and whether they have anything in their life-history corresponding to a sexual process. Not knowing that, we cannot evaluate the possibilities of variation and mutation, questions which lie at the root of many problems of epidemic disease; nor can bacteria satisfactorily form the subjects of a number of biological experiments for which their small size and rapid multiplication so admirably fit them. And this state of affairs is due to the fact that bacteria have been studied as causes of disease; no one has loved them for themselves. Practice has outrun theory so far that practice is itself coming to a dead end.

Apart from its technical medical aspects, much the same is true of the rest of pathology as anyone may see by comparing Coats's text-book with the latest edition of McCallum. Except in detail progress has been very slow; I need not labour examples.

Technological and General Pathology.

We must then return to the outlook of Virchow and Cohnheim and the other great masters who taught us that pathology existed and was worth our attention; I do not imagine that it ever occurred to them that it was nothing more than an appendage of medicine. The medical aspects are at present in most places fairly well satisfied; it is the more general outlook which needs attention. Our history will, I imagine, reproduce the history of chemical study. Fostered a good deal in medical schools in early days for its pharmaceutical importance, it has now developed into the chemistry which is prosecuted in universities and the chemistry to which schools of technology devote themselves—not two separate sciences but two ways of looking at the same science which, incompatible in temper to a degree which makes it impossible for them to live happily together, yet freely communicate with one another, have all knowledge in common, and unite into a complete and harmonious whole. Correspondingly we shall have a technological pathology in the medical school and a general pathology in the science faculty. There will be no divorce of clinical from scientific work—I am particularly anxious that you should not think I am advocating that—but each of the partners will be free in the service of the other. "Next," says Dorothy Osborne, "to doing you a service my greatest pleasure is to receive one from you"; that is the relation which should exist between medicine and pathology.

If we try to direct this piece of evolution by deliberate effort in detail we shall be likely to make something of a mess of it. What we need is the right spirit, and with that all these things will be added to us. But two or three things are obvious. In the first place much of what is now called pathology must be transferred to medicine and hygiene where it properly belongs. Especially should that curious hybrid "clinical pathology" be brought to an end. It has been an extraordinarily useful makeshift, but it is pathologically sterile and has other mulish qualities, and being essentially diagnosis, should be distributed between the appropriate clinical subjects. This transference has begun, its need is widely recognised, and in due course, no doubt, it will be complete. The change is made easy by the establishment of the whole-time clinical departments which, if only people will have patience, are going to transform the whole atmosphere of our medical schools. Similarly in hygienic bacteriology, diagnosis should pass to the health officer and the scandal of university departments engaged in trade, prevalent enough in England, ought to be stopped. In each case the change will be much to the advantage of both parties: both the clinician and the medical officer of health will gain by having the work in their own hands, and the pathologist will be free of a mass of dull work of which he seldom sees the real significance and which at the best affords a placid occupation for unimaginative minds.

The Two Sorts of Pathologists.

Many of my pathological friends will, I know, object strongly to these proposals. There are roughly two sorts of people who profess and call themselves pathologists—those whose real heart is in medicine, with all its human fascination and its individual interests, and those who are in pathology because they have had it laid upon them to try to know about the reactions of live things to injury and disease, without any more particular reference to human welfare than all of us selfish humans have in our anthropocentric world. I have no wish to start a heresy hunt, but it is plain that in the redistribution of work which I have indicated the former class will go where their treasure is and join clinical departments.

Comparative Pathology.

And in the second place, we must widen the scope of the pathology which will in this way be freed from much that does not really belong to it. When you come to think of it, it is really fantastic to try and deduce general rules from an intensive study of man and casual observations on the few species of animals which we find convenient, for human work, to have in our laboratories. It is curious how often a more generalised pathology has been advocated and how little it has been practised. Hunter, Paget, and Macewen are names which will appeal to the most practical of surgeons; they all laid stress on making the field of our study wider; few have listened to them. What we need is a comparative pathology, and it will transform our notions of disease and injury as the comparative anatomy of last century revolutionised zoology. There is no time to enlarge on this necessity; let me just quote three examples. The site distribution of tumours is a matter on which there has been a good deal of talk; we happen to know that the distributions in the mouse, the dog, and the cow are different from one another and quite different from what obtains in man. We clearly ought to know what it is in as many animals as possible before we draw any conclusions of more than specific scope. The anatomical reaction to injury is one of the greater topics of pathology. How much will you find in our text-books on plant galls which exhibit an exquisite specificity of anatomical reaction which is quite unrepresented in animals? Of the physiology and pathology of galls little is known and their study is still in the taxonomic stage. How often is it realised that the chemical methods of defence against parasites of which we have to read so much are an evolutionary development attained to only as warm-bloodedness was achieved, and that they are of importance only among that small and very specialised group of live things? The importance of studying animals other than man is well illustrated by the work which Miss M. Slye has done on her town of mice at Chicago; quite apart from tumours, towards which her study is particularly directed, she has a mass of interesting data about the pathological changes to which those animals are subject and the causes of their death. Dr. H. Fox, in Philadelphia, has lately shown us what good use may be made of zoological gardens, and Dr. N. S. Lucas and others have made a beginning along the same lines in England. Veterinary studies have contributed something, and Dr. Theobald Smith gives us an example of what may be done by observing a herd of cattle as a health officer observes a human population. But "comparative pathology" is not always what it might be; too often it is simply the technological study of diseases of importance in domestic animals of economic value, and it is given a name which will satisfy the academic pedant and for its prosecution excuses are made which will please the practical agriculturist and with luck attract endowments. Anyone who wishes to see what an all-round conception of general pathology can be should study the writings of that good man and great scholar, Samuel George Shattock, who died a few months ago after 40 years devoted service to his science.

And thirdly, something may be done educationally. Medical instruction has been mauled about enough for the present; I think we had better leave it alone for a while and see how our reforms work. But pathology should no longer be a purely medical subject and courses should be available for other than medical students, first perhaps for the biologist, to whose subject pathology is more germane than has been realised, then for the philosopher. It would do us teachers a deal of good to have to guide into pathology students who neither know nor intended to know any medicine; we should, I am sure, reap a good harvest of fresh ideas. A beginning in this has been made already; at Cambridge, under Prof. H. R. Dean, pathology has got into the natural science tripos; at

Manchester Prof. W. W. C. Topley, and at Leeds Prof. J. R. McLeod are exploring the possibilities of a generalised bacteriology, and there are, no doubt, other advances being made along the same line which I do not know of. Feeling a little nervous that the programme which I have sketched might not commend itself to Prof. Oertel, I was delighted to learn on getting here that McGill is adopting this wider point of view and recognising pathology as a subject for the M.Sc. and Ph.D. degrees. Whether many students will present themselves for these new courses remains to be seen, but that is a factor which should count for little in any scheme of university reform.

Conclusions.

Well, here is your new building; may you have a happy life in it. William James says somewhere, you will remember, that a deed well done can reach perfection only if it is well received. Those who have provided this institute have done their good deed; it remains with you to make it perfect by your good use of it. I am sure you will.

THE

Bradshaw Lecture

[ABRIDGED]

ON THE

PREVENTION OF ACUTE RHEUMATISM.

Delivered at the Royal College of Physicians of London on Nov. 4th, 1924,

By F. JOHN POYNTON, M.D., F.R.C.P. Lond.,
PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

[After referring to the study devoted by Fellows of the College in the past to the subject of acute rheumatism, and specifically to the work of those who had been his own teachers, Dr. Poynton proceeded to discuss the difficulties that beset the problem of prevention. He said :—]

The prevention of acute rheumatism is faced with many difficulties, and I think the more closely it is studied the more apparent these become. The first of these is nomenclature, for acute rheumatism may be the most insidious of maladies. Yet if we leave out "acute" and use the term "rheumatism" we are at once overwhelmed by the various disorders with which we are confronted, and if we abandon the term "rheumatism" altogether we shall have great difficulty in finding a substitute.

The next difficulty is concerned with the ætiology of acute rheumatism considered as an infective disease. This has a most important bearing upon the possibilities of prevention, but is at present in a state of uncertainty. I believe I shall not be wrong if I put the position somewhat thus. Many who have given the most attention to the subject recognise the importance of the strepto-diplococcus, but do not think that it affords a complete explanation and would look elsewhere—to some filter-passer, for example. Neither do I look upon this micrococcus as a complete explanation, but I do not anticipate the discovery of another infective agent. I look for help from the unravelling of the tangled skein of the secondary factors which combine with the micrococcus to produce this specific disease.

Even if we admit that acute rheumatism is due to a specific infection we find ourselves confronted by further problems, among which are the many predisposing factors to the infection, such, for example, as heredity, environment, and nerve strain.

Again, our conception of the disease is still deficient in two particular directions; we have very little accurate knowledge either of the life-history of such an infection when once it has gained access to the human frame, or of the influence of the tissue-characteristics and habits of the patient upon its course. On this account I have always included in any scheme for the prevention of acute rheumatism provision for opportunities for research.

The varied symptoms of the disease dependent upon the various important organs attacked constitute yet another difficulty, though one which must steadily diminish with increasing knowledge. Then there is the difficulty of treating this disease with success, and upon this point, so far as children are concerned, I unfortunately find myself at variance with many able physicians. Except for the relief of pain, my experience as to salicylate of soda and other members of that group has been so unsatisfactory that I have no hesitation in stating that in the most formidable cases of carditis in the young my best results have been obtained without their use.

Reasons for Attempting Prevention.

It may be asked whether it is not premature in the face of so many difficulties to enter upon elaborate attempts at prevention, but to this I believe we may safely answer "No," and for these reasons: 1. It is generally admitted that acute rheumatism is a cause of three disorders of national importance—first and foremost, organic heart disease, secondly chorea, and thirdly arthritis and fibrositis. 2. It is not a rare disease but a frequent one, and the heart lesions, chorea, and arthritis are common manifestations. 3. It is much more rife in the poorer classes, and the study of poverty with a view to its amelioration is undoubtedly a function of a civilised country. 4. Again, it is a disease which certainly responds to careful supervision and treatment, and there are at the present time flaws in our supervision capable of at least considerable mending. 5. Lastly, it is not a disease of the old and failing, but one that kills and maims children and young adults, damages useful citizenship, and wastes much money spent on education. A recent Blue-book on the subject of the "Incidence of Rheumatic Diseases" in its quiet pages supports all the statements I have just made.

The Medical Practitioner.

In the prevention of acute rheumatism it is clear that the doctor in general practice must, as in all the great problems of preventive medicine, take a prominent and essential part, not only in early diagnosis and treatment, but in the supervision of those who have suffered from the results of the disease. It is not too much to say that if this branch of our profession failed us, which is not thinkable, the whole fabric of prevention would be unsound at its foundations. The responsibility for adequate training in the clinical and pathological aspects of the disease rests with the great teaching centres. To them we must look for rousing in the minds of future practitioners an enthusiasm for the opportunities they would have to help to make a success of a scheme which holds out such great possibilities.

The Hospitals.

Our hospitals, and in particular the children's hospitals and the children's departments in the general ones, would in any scheme hold, I presume, the same position they do now, and would also carry out the training of the undergraduate students in the recognition of the disease and its manifestations and the methods of prevention and immediate treatment.

The out-patient departments of hospitals would be mainly consultative. They would in the poorer cases take the place of the general practitioner as supervisor, but their most essential functions would lie in deciding a difficult diagnosis, in admitting to the hospital, and in advising doctors and patients as to the best procedures at the moment.

A Weak Point.

We are now met by a weak point in our management. It is common knowledge that recovery from acute rheumatism is often slow, and that neither cardiac inflammation nor chorea are conditions suited to ordinary convalescent homes. The alternatives are to keep them in a sick ward in the middle of a great town or to send them home. The weakness, then, in the present position is twofold: we are not doing the best for our rheumatic patients, and we are using beds in expensive institutions which are required for urgent or obscure cases.

Recovery Hospitals.

Each year it is becoming more evident that the great cities, and London in particular, require recovery hospitals in the adjacent country in vital touch with the mother hospitals. In an ideal hospital of this type the cases would have the necessary time for convalescence, would, in the surrounding grounds, be trained for physical exertion, and eventually be classified according to their ultimate degree of recovery, and they would also—a point of great importance—*continue their education.* The history of acute rheumatism would be continued in a sequel to the first hospital notes, and eventually the children returned to their parents with a short practical statement as to their capabilities.

One link in this chain requires the most careful consideration. There must be an intimate and vital connexion between the parent and recovery hospital. If the latter once drifts into a second-rate soul-less abode for "uninteresting cases," its value is lost, and it becomes a monument of inefficiency.

Pioneer Attempts.

Pioneer attempts have already been made in this country, as for example, at the Edgar Lee Home (Stonebridge Park), Broadstairs, at the Chiene Hospital, in Birmingham, and at Bristol and doubtless elsewhere. The Invalid Children's Aid Association in particular has taken a prominent part in this movement, and has recently started a home of 50 beds for females up to 14 years and males to 7 years of age at Hartfield, in Sussex. I have the honour to be one of the hon. visiting officers, and, though it is too soon to make a report on progress, I may remark that at present the results are encouraging. The gains in weight, the absence of attacks of rheumatism, the improved physique, and the happiness of the children who are continuing their education and living and sleeping practically in the open air, make me hopeful that we are entering upon a real advance in the treatment of rheumatic heart disease.

THE MINISTRY OF HEALTH.

Leaving now the rôle of hospitals, I come to the far-reaching activities of the Ministry of Health, Board of Education, and medical officers in the London County Council schools. Hidden away in their not superficially attractive reports there are some of the most fascinating chapters in modern medicine.

Official Medical Supervision: Infant Welfare.

During the first years of life we have the infant welfare centres, from 5 to 14 years the school medical officers, and from 16 years onwards the National Insurance. There are two breaks in complete continuity, one between the second and fifth years, and the other between the fourteenth and sixteenth years. The break between the second and fifth years, which in theory does not exist but in practice does, will doubtless be eventually bridged, and already is encroached upon, on the one side by the infant welfare organisation, and on the other by the school authorities. I have given considerable time and attention to the subject of acute rheumatism under 5 years of age, and though I am not implying that the disease is frequent then, I am sure that it occurs more often than is generally suspected, and that it is liable in these early years to cause great damage to the heart. Supervision between 2 and 5 years should eventually throw light on the earliest phases of the disease.

School Medical Service.

The period of *school life* is by far the most important in the history of acute rheumatism in this country. The incidence of the disease rises rapidly after the fifth year to about the tenth, and chorea, which I have seen as early as nine months, and occasionally in the second year, comes now to the front. It follows that the School Medical Service must take an ever-increasing share in the problem of prevention.

The appearance of chorea during the school age demands, I think, special attention. This manifestation is a most interesting one, for on account of the peculiar movements it becomes the most sensitive clinical index we have of active rheumatism, and it is also the manifestation which most frequently occurs alone and has a most striking sex incidence. Accordingly the study of the course of chorea gives us a very fair insight into the general behaviour of acute rheumatism, and when we recall that repeated chorea is a frequent indication of an early mitral stenosis, we suspect that both these lesions are pre-eminently the result of the smouldering activity of infection.

There is a passage in the report of the Chief Medical Officer of the Board of Education which deserves particular attention. It comes from a report in 1923 of the consultative committee on the differentiation of the curricula for boys and girls respectively in secondary schools. This committee draws attention to the present danger to health connected with the strain of examinations and of accomplishments added to the boys' curricula, and they note the relatively heavy household duties devolving at this age on many girls. I see in this passage light for the future and a sense of the reality of things, which cheers me almost as much as the sight of a flowering shrub upon the walls of one of those gaunt buildings with which we are so familiar.

Early Adolescence.

Still keeping our attention to the official side of the medical problems, we pass to the age of early adolescence, 14–16 years, and to the time when the child leaves the supervision of the school medical officer and has the choice of occupation immediately ahead. Everyone recognises that this is a critical period in life, and it is unfortunate that just at this time there is a break in the continuity of official supervision. The school medical officer is left and the National Insurance has not begun.

Factory Surgeons.

We come now to the factory surgeons, who are some of them school medical officers, and all of whom are encouraged by Sir George Newman to coöperate closely with those officers. These examine adolescents at 16 years entering factory life, and under that age those who enter such employment, including certain specified workshops, as requires an earlier training. Occupations which do not require a certificate of fitness constitute a weak link in the chain, perhaps more apparent because some three years ago the gap between 14 and 16 years was practically closed by the day continuation schools. The axe, however, fell, cutting through this slender neck and the young head of the school medical period tumbled into the basket of economy.

The report of the Departmental Committee issued this year shows, moreover, that the Factory Act has not proved satisfactory. In 1920 it was found that nearly 8000 individuals were rejected in the United Kingdom by the factory surgeons on medical grounds, and 576 of these for diseases of the heart and lungs. This clearly points to some leakage in that period between leaving school and applying for factory employment.

We see from this short outline of the official side of the medical problem that one of its most important duties is akin to that of the signal-men on our railway lines; at certain stages along the line of life these officials indicate danger and pull up the train. The medical practitioners and hospitals clear the track and endeavour to prevent further breakdowns.

Works Doctors.

There is another link, and one of increasing value in the chain of prevention. This is the appointment by many large industrial concerns of special medical officers, matrons, and nurses to supervise the health of their staffs. There cannot be any doubt that this link, forged though it may be on the anvil of strict business by the hammer of self-defence, must do great good, particularly when that service is far-seeing and kindly.

The General Practitioners.

As I have already stated, throughout their early life the doctor in general practice is taking an unobtrusive yet important part in attending rheumatic children, but as Dr. Carey Coombs has suggested, they could offer more special assistance by the formation of voluntary groups in various districts around some great city. In this way some point under investigation in the city hospital such as the incidence of the disease in certain areas or the appearance of a local epidemic, would enable them to use their special knowledge and experience.

When the insurance age is reached and, indeed, in every stage of life, the general practitioners who give time and interest to this particular subject can continue to furnish valuable data not otherwise to be obtained.

INCREASED COÖPERATION.

This raises a somewhat delicate subject, and my remarks must be looked upon as an expression of a purely personal view. Taking a broad outlook, there are three great medical forces in this country. The hospitals, with a magnificent history of past and present work but financially unstable; the Ministry of Health, young and powerful, with immense resources and advantages; and the general practitioners, with the all-important assets of experience of the dawn of disease and intimate acquaintance with their patients. Each can take a most valuable part in the prevention of acute rheumatism, but greater results are to be expected if these forces can be drawn closer together. Greater organisation between them would, in my opinion, enhance the value of the School Medical Service, which appears to me often to be in the position of a doctor whose patient has been under a consultant's care and returned to him without a note of guidance. Looking to the future for one of these forces I can only see one fate, and this is that the hospitals become the strong right arm of the Ministry of Health. I use the word "strong" advisedly, for to be strong there must be wide liberty of thought and action, and not the suffocating growth of "officialism."

For my part I should like to see skilled officers, somewhat on the lines of our hospital medical registrars, but representatives of the Ministry of Health, linking up the cases and notes of the rheumatic patients in our hospitals with those of the school medical officers, and bringing to us hospital physicians the particular lines of thought and investigation under the consideration of the Ministry and in turn keeping the latter in intimate touch with hospital activities. In another direction, also, there are great possibilities, and that is in the coöperation of hospitals and almoners with the Board of Education and their army of voluntary workers and the child care committees. From the standpoint of the rheumatic children they would give great assistance in following up these cases when they leave the hospitals.

ENVIRONMENT.

The influence of environment upon the incidence of acute rheumatism is one of the problems in prevention which appears to me particularly to need more extensive investigation. This aspect is one which I always associate with the honoured name of Sir Arthur Newsholme, who showed us the importance of urban life as a factor in causation. Damp and cold houses and districts tend to make acute rheumatism drift into a chronic course, and it is my belief that a child returning from hospital after an attack to such surroundings is certainly in great danger of chronic invalidism and likely to die in a few years. I am also most suspicious of cold winds when there has been a spell of hot weather and much dust in the towns, this combination producing tonsillitis and increasing the incidence of acute rheumatism. The medical officers of health would have a prominent part in this investigation, and already to my knowledge they are taking the problem in hand; the care committees, too, should prove invaluable.

NOTIFICATION.

I believe that a partial and temporary notification might be helpful. General notification in the present state of our knowledge would probably lead only to great expense and confusion. It might, however, be advisable to notify acute heart disease in childhood or chorea, or, again, obvious cases of acute rheumatism up to a certain age and for a limited time.

Contagion is an aspect which at present I should not care to be brought into prominence, believing that it does not take an important part in the history of acute rheumatism.

EDUCATION OF THE PUBLIC.

Two directions suggest themselves by which we can better instruct the public: the first, by means of educational leaflets and lectures, to bring home to parents, patients, teachers, and labour employers the dangers of the disease; and the second, to assist them in choosing industrial occupations and in recognising the limitations of employees who have been partially maimed by acute rheumatism. The Ministry of Health could, I believe, render a great service if they would publish a leaflet for the guidance of the public, setting out in simple terms the dangers of acute rheumatism, together with some simple instructions. In the other direction, the assistance of the public in the problem of employment, we require the best possible organisation for providing information for the guidance of those who have rheumatic children to place in life, such as schedules of suitable employments.

It certainly should become increasingly difficult for such a case to occur as recently came under my care. This was an undersized girl of 20 years with obvious mitral stenosis who was working as a bottle labeller underground, often in wet clothes, and lifting heavy cases. As a result she was admitted with a complete cardiac breakdown from which she has never recovered.

THE LOCAL FOCUS.

The next point is the removal of local focal infection as a factor in prevention. On June 7th, 1900, a man, aged 28 years, came to St. Mary's Hospital suffering from a sore-throat. The condition was one of acute tonsillitis and he had mitral and aortic disease, arthritis and muscular pains. There was a previous attack of rheumatic fever four years before. Dr. A. Paine, by plate culture, isolated a strepto-diplococcus morphologically and culturally indistinguishable from that we had isolated from the lesions of acute rheumatism. Intravenous injections into a rabbit produced acute aortic and mitral endocarditis. Fitz-Meyer, two years later, by extensive experiments supported these results, and later with Mr. George Waugh we repeatedly verified the ability of this micrococcus obtained from unhealthy tonsils to produce cardiac and arthritic lesions without any previous injury to the valves. This was the birth of the "local focus" in rheumatism.

No one can be *more* convinced than I am that the rheumatic infection has one important site of entry into the system, through diseased tonsils and particularly those which resemble in their deep lacunæ culture tubes. No one probably is *less* convinced than I that wholesale removal is indicated in the rheumatic child, or that the removal of the local focus shuts the door. Nature is not so easily managed, and I have seen severe carditis in a first attack occurring some years after a complete enucleation. Recent American statistics bear out this experience. I look upon the tonsils as an important barrier, but as no man is more dangerous than a clever man who has lost his capacity, so are badly damaged tonsils a constant source of danger. Careful treatment of the throat, naso-pharynx, and teeth in the prevention of acute rheumatism will be, in my opinion, a permanent factor. More investigation is required to determine other local foci as equally definite.

Research.

That further research is essential to advance the prevention of acute rheumatism is generally admitted. Opinions as to the best method for obtaining results will naturally differ, and I can but express my own views. I think there should be some institution in which the study of "rheumatism" should be continued uninterruptedly. In a centre such as London I would have this institution concerned with the entire problem of rheumatic affections, for it is my experience that in research one is liable if following a particular line to reach a dead end; some fact or some technical detail is lacking or the brain becomes wearied. Then one needs to leave that line for a ime and to work in other directions, returning later refreshed with new ideas or with new equipment. The problem of "rheumatism" would always have open spaces; now there might be fresh light thrown on malignant endocarditis, now a discovery in the bacteriology of rheumatoid arthritis or some chemical advance bearing upon fibrositis. Thus the vitality of the research would be kept active. Such an nstitution could be organised for training investigators and putting them in touch with our great hospitals and infirmaries, and would have at hand an ample literature. I admit the scheme is ambitious, but I am looking ahead.

A PRECIPITIN METHOD FOR THE STANDARDISATION OF "OLD" TUBERCULIN

AND THE EXPRESSION OF RESULTS IN STANDARD UNITS.

By GEORGES DREYER, C.B.E., M.A., M.D., F.R.S.,

AND

R. L. VOLLUM.

(From the Department of Pathology, University of Oxford.)

Old tuberculin, since its discovery by Koch in 1890, has been used extensively as a diagnostic, prognostic, and therapeutic agent in tuberculosis. Unfortunately, the proportion of the active principle of tuberculin present in different samples is not constant—as judged by the reactions they produce—but varies considerably, even when the method of preparation is more or less standardised. It is apparently influenced by several factors, such as the strain of *B. tuberculosis* used, the composition of the medium, the age of the culture, and the method of concentration. Although the active principle has not yet been isolated, numerous methods have been used o estimate the relative amounts of it present in different samples of tuberculin. The fact that its use is attended with some danger—an excessive dose may produce a severe general reaction—makes it necessary, in clinical work, to know with reasonable accuracy the strength or toxicity of each sample used; and in scientific work it is, of course, imperative, in order to obtain comparable results.

Methods of Standardisation in Present Use.

The methods of standardisation in vogue at present are:—

1. The determination of the lethal dose for tuberculous guinea-pigs. This is the official German method as used by the Staatsinstitut für Experimentelle Therapie in Frankfurt A/M.[1] [2] [3]
2. Von Lingelsheim's intracerebral method on normal or tuberculous animals.[4]
3. The quantitative von Pirquet, and the intradermal reaction on tuberculous guinea-pigs.[5] [6]
4. The quantitative von Pirquet on human tuberculous subjects.[7] [8]

The methods depending on the use of tuberculous animals have certain inherent disadvantages. Tuberculous guinea-pigs, even though infected at the same time with the same amount of inoculum, may show great variation in the extent of the resulting lesions. And even when the lesions are apparently similar the animals may show great variation in sensitiveness to the same dose of the same tuberculin. Therefore, in order to obtain reasonably accurate results it is necessary to use a large number of animals—which makes the method troublesome and expensive. These disadvantages apply even to the intradermal test, where both the standard and unknown tuberculin are used on the same animal, because different parts of the skin vary greatly in sensitiveness. Furthermore, unless the animal is in exactly the right stage of sensitisation the reaction may be very ill-defined; and even at best it is often difficult, if not impossible, to distinguish between two lesions caused by two different dilutions of the same tuberculin, unless the one is at least double the strength of the other.

Von Lingelsheim's method has the advantage that it can be used on normal animals, but it is applicable only to tuberculin which is free of glycerine, the latter being highly toxic for the nerve cells. The most satisfactory in vivo test is probably the quantitative von Pirquet, on human cases of tuberculosis, as modified by Ellermann and Erlandsen,[7] or by Cummins.[8] Even in this test it is difficult to distinguish between the lesions produced by the same quantity of two dilutions of the same tuberculin of less than 100 per cent. difference in strength. Furthermore, the test may be accompanied by some inconvenience and discomfort to the patient, as the lesions frequently persist from a week to a month before disappearing.

In consideration of these difficulties, it would obviously be of great advantage to have an in vitro test for the standardisation of old tuberculin. The complement-fixation reaction has been applied for this purpose, but the number of reagents employed and the difficulty of standardising them bring in several unavoidable sources of error which would tend to preclude it from being a satisfactory quantitative test.

It seemed to us that an in vitro test, involving the least possible number of reagents, whereby it would be possible readily and accurately to compare tuberculins of unknown strength with an established standard would be desirable, and that a precipitin test was likely to fulfil these requirements.

Precipitating Power of a Serum for Tuberculin.

The first difficulty which presented itself was to obtain a serum of high precipitating power for tuberculin. Calmette[9] and others have prepared sera which would precipitate tuberculin, and we obtained two samples of serum which had been prepared by immunisation of a horse with the whole bacillus. We found that their precipitating power for tuberculin was relatively weak, and furthermore, as Calmette had previously found, that the precipitation was not specific, since the serums precipitated mallein to about an equal extent. It was found that by the use of diaplyte (defatted) *B. tuberculosis* vaccine[10] to immunise a horse, a serum could be obtained which had a high precipitating power, not only for its specific precipitinogen, obtained by digesting the diaplyted bacilli with trypsin, but also against old tuberculin. It did not precipitate mallein, diphtheria toxin, or concentrated broth controls; its precipitating power for tuberculin was from 200 to 800 times as strong as that of the other serums which we tried.

However, the preliminary quantitative experiments showed that in comparing two tuberculins, very discrepant results were obtained, depending on the relative quantities of serum and tuberculin used. Using concentrated tuberculin, or dilutions up to about 1 in 50 with a constant quantity of serum, the precipitation increases with decreasing amounts of tuberculin ; but with high dilutions, ranging from 1 in 500 to 1 in 30,000, depending on the strength of the tuberculin, the degree of precipitation decreases with the quantity of tuberculin present. This being the case, it became necessary to work out in detail the whole quantitative relationship between serum and tuberculin. The details of these experiments, which are chiefly of theoretical interest, will be published later. The practical outcome of them was that it was found possible to measure with considerable accuracy the strengths of different dilutions of the same tuberculin or of different tuberculins.

Technique.

The technique which we have evolved for the standardisation of tuberculins by the precipitin method will now be described in detail.

(A) *Reagents and Apparatus Required.*

(1) Standard tuberculin ; (2) standard precipitating serum ; (3) normal saline for diluting serum and tuberculin ; (4) Dreyer agglutination tubes and stands ; (5) accurately graduated measuring pipettes, Dreyer dropping pipette, and dilution tubes ; (6) water-bath, 37·5° C. ; (7) artificial-light arrangement for reading tubes against dark background ; (8) six-magnification hand lens.

Details are as follows :—

1. The standard tuberculin we have used is the German Standard Tuberculin, kindly supplied by Geheimrat Prof. Dr. Kolle. It is the standard used by the Staatsinstitut für Experimentelle Therapie, Frankfurt A/M.

2. The precipitating serum, as stated above, was obtained by immunising a horse with diaplyte *B. tuberculosis* vaccine. The horse received weekly injections, intravenously, of doses increasing from 0·1 mg. to 225 mg., over a period of three months.

3. The sterile normal saline is prepared by dissolving 9·0 g. of chemically pure sodium chloride in 1000 c.cm. of freshly distilled water, and immediately sterilising in the autoclave.

4. The agglutination tubes employed are those used for the Dreyer agglutination technique. The inside diameter of these tubes is 5·5–6·2 mm. ; the outside diameter is 6·6–7·2 mm., and the length is 58 mm. The bottom is conical and the top is flanged to facilitate filling. These tubes, and all other glassware, must be thoroughly cleaned in acid, and then washed in distilled water until all traces of acid are removed. The tubes are then sterilised by dry heat. Agglutination stands containing three rows of 20 holes for agglutination tubes are the most convenient.

5. Pipettes, accurately graduated to *contain* 0·1 c.cm., 1·0 c.cm., 5·0 c.cm., and 10·0 c.cm., respectively, are required. The Dreyer dropping pipette, as used in the standard agglutination technique, has a total length of 19 cm., length of capillary portion, 2·8 cm. ; outside diameter of body of pipette, 5·0–5·4 mm. ; outside diameter of capillary portion, 2·36–2·41 mm. ; bore of capillary portion, 0·5 mm. The dilution tubes are test-tubes, 18 by 2·5 cm., without lips. They are sterilised by dry heat without plugging.

6. The water-bath must be regulated to maintain a constant temperature of 37·5° C., and should be provided with a device to keep the water-level constant. A satisfactory arrangement is described by Dreyer and Ward.[12]

7. An artificial-light arrangement for reading the tubes is essential, and it should be used in a darkened room. An adjustable lamp, fitted with an ordinary plain conical shade, covered on the outside with dull-black paper, is suitable. The end of the bulb should not project appreciably beyond the edge of the shade, and the lamp should be so arranged that the observer does not look directly into the light. The tubes to be read are held against the edge of the shade, the lower end tilted towards the observer, and the meniscus of the fluid in the tube should be slightly above the lower edge of the shade. It is desirable to place a dull-black cardboard on the table, and another resting against the farther edge of the lampshade, so that the observer may look through the tube against a dark background. A frosted bulb of 20 candle power is satisfactory. A stronger light obscures the finer degrees of precipitation, and should not be used.

8. A compound six-magnification hand lens of reputable make.

(B) *Method of Diluting the Tuberculin.*

Seven dilution tubes are placed in a stand and sterile saline is measured into them, the first receiving 9·9 c.cm., and each of the others 10·0 c.cm. ; 0·1 c.cm. of tuberculin is measured in the 0·1 c.cm. pipette. The outside and tip of the pipette are wiped free of tuberculin, and the contents are blown out into the first tube. The viscous tuberculin sticks to the walls of the pipette, and must be washed out by carefully aspirating the mixture in the tube and blowing out again. To ensure thorough washing of the pipette, this should be done 30 times. For this purpose it is convenient to use a teat. If the supply of tuberculin is not limited, this first dilution may be made in a similar manner, using 99 c.cm. of saline and 1·0 c.cm. of tuberculin. Having thus obtained a 1/100 dilution, further dilutions of 1/300, 1/900, 1/2700, 1/8100, and 1/24300 are made as follows. With the 5·0 c.cm. pipette measure, 5·0 c.cm. of the 1/100 dilution into tube 2. Wash the pipette in the dilution by aspirating several (at least 10) times, and after thorough mixing, carry over 5·0 c.cm. of this dilution into tube 3, and so on until the required number of dilutions has been made.

(C) *Method of Setting Up Test.*

Place a row of 20 agglutination tubes into the stand. With the standard dropping pipette, measure out into the tubes the following quantities of saline, tuberculin dilution, and serum dilution in the order named. (See Table I.)

TABLE I.

Tube No.	Saline (drops)	Tuberculin.		S.S. (drops)	Tube No.	Saline (drops)	Tuberculin.		S.S. (drops)
1	3	12	Drops 1/300	5 1/4	11	3	12	Drops 1/2700	5 1/4
2	5	10		,,	12	5	10		,,

S.S. = Standard Serum.

One and the same pipette must be used throughout the whole operation. When changing from one reagent to another, or from one dilution to another, the pipette should be carefully washed out with distilled water, and dried by washing through with acetone, followed by gentle heating over a Bunsen burner. The use of an ordinary suction pump will greatly facilitate the washing and drying of the pipette.

When the reagents have been added to the tubes shake each one thoroughly in order from right to left—i.e., beginning with the tube containing the highest dilution of tuberculin. Place the stand in an *open water-bath* (not in a dry-air incubator) at 37·5° C., and arrange the water level so that the *column of fluid in the tubes is only one-half to two-thirds immersed*. Precipitation is greatly facilitated by this procedure.

It is desirable to put up each of the unknown tuberculins to be tested and each of the standards in duplicate. Two or more standard tuberculins should be used in each test, but if only one is available four or five dilutions of it should be made up independently to secure a true average of the readings of the standard tuberculin. As a general rule, it is necessary to put up only 15 tubes in each row—using the dilutions 1/900, 1/2700, and 1/8100 or 1/2700, 1/8100, and 1/24300. With strong tuberculins it is necessary to use the higher dilutions, and all but the very weak ones will show a good reaction in the 1/900 dilution after nine hours' incubation. In the case of very weak tuberculins on the other hand, one may have to begin with dilutions of 1/100, 1/300, &c. If the lower dilutions of strong tuberculins are used, a precipitate will come down almost immediately after the serum is added, but different tuberculins are found to have different reaction times, and the end-point is not usually reached until after nine hours' incubation. If left for a longer time the precipitation loses some of its sharpness, and is more difficult to read ; also the danger of infection becomes greater.

(D) *Reading of Results.*

The tubes are read in the manner already indicated under (A) 7. To secure uniform readings by different observers it is desirable to use permanent tubes showing standard and trace precipitation for comparison. The principal terms used in describing the different degrees of precipitation met with are : Total (T), standard (S), trace (tr), and nil (0). Total precipitation indicates a condition where the fluid in the tube has become quite clear, with a relatively large bulk of precipitate settled down at the foot of the tube. Standard indicates a degree of precipitation that can be seen readily with the naked eye. The fine particles are evenly distributed, of uniform size, and definitely separated from one another. Trace is the term applied to a very fine precipitation, barely visible to the naked eye, but readily visible with the six-magnification lens. Nil indicates that no visible precipitation has taken place, though the fluid may show some opacity.

Naturally there are degrees of precipitation which fall in between total, standard, trace, and nil; total minus (T –), where the fluid is clear, and the particles are large and well separated, and some have fallen to the foot of the tube. On either side of standard precipitation there is standard plus (S +) and standard minus (S –). In the former the particles are larger than those seen in standard precipitation; hey are uniformly distributed, and clarification is more marked; in the latter is seen a finer precipitation than standard. Similarly, there is a trace plus (tr +) and a trace minus (tr –), the former representing something more han a trace but less than a standard minus, and the latter being a very fine degree of precipitation visible only with the ix-magnification lens. In addition, a condition where there s only a very slight opacity, or an extremely fine degree of precipitation, barely visible with the six-magnification lens is designated as trace query (tr ?).

(E) *Expression of Results in Standard Units.*

The strengths of all tuberculins are expressed in standard units. We have chosen the Frankfurt standard tuberculin as the standard comparison, and have arbitrarily assigned to it a value of 100 units per c.cm. The value of any other uberculin in standard units is inversely proportional to the mallest amount required to produce the same degree of precipitation as the standard with the same quantity of erum under the same conditions. Thus, if twice the quantity of tuberculin X is required to produce the same degree of precipitation as the standard tuberculin under the ame condition, its strength is one-half of the standard—e., 50 units per c.cm.

(F) *Calculation of Units.*

The unit value is calculated from those tubes in the eries which show standard and trace precipitation respectively. The unit value is calculated for each of these two tubes separately, and the average is taken as the unit value of the tuberculin. If there are no tubes in the series showing exactly standard and trace precipitation, it is necessary to nterpolate for these values—e.g., if tube 4 shows S + nd tube 5 shows S –, S would be intermediate between hem. In Tables II., III., IV., and V. are shown the method of recording readings and calculating results.

TABLE II.—*Examples of Readings.*

Tube No.	Tuberculin—				
	Quantity in drops.	Standard.	"A"	"B"	"C"

TABLE V.—*Average of Standard and Trace Calculations in Tables III. and IV.*

Standard tuberculin = 100·0 units per c.cm.
Tuberculin "A" = 33·5 ,, ,,
,, "B" = 64·5 ,, ,,
,, "C" = 112·5 ,, ,,

For the accurate measurement and standardisation of tuberculin it is desirable—as in all other quantitative work—to make several determinations and to take the average as the final figure. We find that at least five determinations are required to give accurate results. Fresh dilutions should be made for each determination. The standard tuberculins must, of course, be put up each time with the unknown tuberculin, because slight variations in the time of incubation and in the temperature and water level of the water-bath have an appreciable effect on the degree of precipitation. Although the actual readings of any tuberculin may vary slightly from day to day its value, relative to the standard, should remain constant.

(G) *Precautions to be Observed.*

1. The serum must, of course, be absolutely clear and sterile. We have found that the Seitz laboratory filter is very efficient and satisfactory for removing sediment and contamination from serum, and it does not take out the precipitin. The serum must *not* be heated. The extent to which a serum may be diluted to give satisfactory precipitation will vary with its strength. The serum we have used gave good results when diluted 1 in 4.
2. Antiseptics, such as phenol, trikresol, or formalin should not be added to any of the reagents, as experiments have shown that when these antiseptics are present in a concentration sufficiently great to prevent bacterial growth, they interfere with the reaction and change the character of the precipitation.
3. The agglutination tubes which are used for the test must be of the diameter laid down. If tubes of larger diameter are used, the character of the precipitate changes and does not give sharp readings.
4. All glassware must be scrupulously clean.
5. The water-bath must be *open* and the temperature must be accurately regulated, and must be kept constant at 37·5° C. The water level must be carefully adjusted, so that only one-half to two-thirds of the column of fluid in the tube is immersed.

Results.

A series of carefully prepared dilutions of a sample of old tuberculin were made up by one of us and labelled *n*, *o*, *e*, *y*, and *x* respectively, and were tested and calculated by the other who did not know the key. In Table VI. are given the actual strength of the solutions, and the values found on a single determination.

TABLE VI.

Tuberculin labelled.	Tuberculin unit per c.cm.	Tuberculin unit per c.cm. found by precipitin test.	Percentage deviation.
n	100	93·28	6·72
o	45	46·58	3·51
e	27	27·59	2·19
y	12	12·12	1·00
x	5	5·04	0·80
		Average	2·84

Having thus established the theoretical accuracy of the method, it was necessary to compare different samples of old tuberculin to see whether the degree of precipitation depended entirely on the amount of active principle of tuberculin present, or if it were influenced by the proportion of peptone, salts, and glycerine in various samples. There appeared to be no correlation between the degree of precipitation and the amount of non-specific material in the tuberculins. Thus it will be seen from Table VII. that the strength of sample British 6 is only about 41 per cent. of sample British 5, while its viscosity was found to be three to four times as great.

In Table VII. are given the results obtained by examining 30 different commercial tuberculins of varying origin, taking the Frankfurt standard tuberculin as our standard. It is at once seen that different commercial tuberculins may vary enormously in strength—namely, from 33·2 to more than 400 units per c.cm. Furthermore, it was found that certain samples of tuberculin—namely, British 2, 3, and 4 alleged to be equal in strength to the Frankfurt standard—varied considerably. These tuberculins were found to contain 135·1, 33·2, and 46·0 units per c.cm. respectively, instead of 100·0. This being the case, it became necessary to test these samples, together with certain others showing great differences in strength by a recognised in vivo method, to find out if the results obtained by the precipitin test were borne out by the in vivo test. In our hands the quantitative von Pirquet reaction on human cases of tuberculosis gave the most satisfactory results, and it seemed likely that from the point of view of diagnosis and treatment of tuberculosis in man by means of tuberculin this method of standardisation should prove of greater value than tests on animals.

In our experiments, Cummins's modification of the von Pirquet reaction was used. A metal plate, 1·5 mm. in thickness, with a circular hole 4·0 mm. in diameter, is pressed firmly on to the forearm, so that the skin seen through the hole presents a slightly convex surface. The epidermis is scratched off within the circle by a sharp surgical needle, exposing the *cutis vera*. The scratching must not be sufficiently deep to draw blood. Two parallel rows of six scratched areas are prepared in this way, and six dilutions containing 2, 4, 8, 16, 32, and 64 per cent. of tuberculin respectively are rubbed gently into the exposed cutis using the blunt end of the needle, which has been previously dipped into the tuberculin. The standard tuberculin is applied to one row and the unknown to the other. The reactions are read at the end of 24 and 48 hours—by direct comparison of the lesions produced by the standard and unknown tuberculin. The intensity of the reaction is judged by the infiltration, colour, pustule formation, &c.

Each series of dilutions of each tuberculin was marked with a different letter, before being given to the persons (A. D. G. and F. G. H.) who carried out the test on the patients. The tests were read independently by G. D. and A. D. G., and the key to the tuberculins was in no case divulged until the final readings had been made.

In Table VIII. are given the result of the in vivo test of ten of the tuberculins recorded in Table VII. The results are expressed in standard units per c.cm., taking the Frankfurt standard tuberculin as equal to 100 units. The letters *a*, *b*, and *c* indicate tests on different patients. Each figure given in columns 3 and 4 represents the average of from two to five readings on the same patient. The individual readings from which the averages were obtained varied in some cases as much as 400 per cent. In columns 5 and 6 are given the average of all readings made by G. D. and A. D. G. respectively, and in the last column the average of all the readings made by the two observers. From the table it is seen that the results obtained by two different persons reading the same test may vary considerably, and that the values found for the same tuberculin when tested on different patients may show marked variations.

F.S. = Frankfurt Standard. Brit. = British. Ger. = German. Amer. = American. Dan. = Danish.

In Table IX. are recorded the results obtained by the precipitin and the in vivo tests respectively. It is seen that in the case of the Frankfurt standard tuberculin, and British 2, 3, and 4, the differences in strength found by the precipitin test is entirely borne out by the in vivo test. On the whole, the results obtained by the two methods run parallel. The average percentage deviation of the in vivo test results from those obtained by the precipitin test was found to be 34·54 for the ten tuberculins recorded.

From the data presented above, it seems justifiable to suggest that a satisfactory in vitro reaction for the standardisation of old tuberculin has been devised. There may be certain possibilities of error, as in the case of the standardisation of diphtheria toxin by Ramon's precipitation method,[11] where it is found that the change of the toxin to the toxoid by chemical or physical influences is not accompanied by any change in the precipitating properties of the toxin. We have been unable to detect any change either in the toxicity, as tested on tuberculous guinea-pigs, or in the precipitating properties of old tuberculin, when subjected to a temperature of 0° C. for six months, or to a temperature of 100° C. for 15 days, or to autoclaving for two hours at two atmospheres. Tuberculin, therefore, seems to be comparatively stable to temperature changes, and under ordinary conditions the precipitation and in vivo tests on any sample should continue to run parallel. If this is borne out by a longer series of experiments, the great advantage of the in vitro test is obvious. The time and expense required is reduced to a minimum, and a very high degree of accuracy can be obtained by comparing each unknown tuberculin with the standard tuberculin using a precipitating serum of standard strength.

In conclusion, we wish to express our warmest thanks to Captain S. R. Douglas, F.R.S., Prof. J. B. Buxton, and Major G. W. Dunkin for preparing the precipitating serum at the National Institute for Medical Research. Also to Dr. A. D. Gardner and Dr. F. G. Hobson for their kind help in carrying out the von Pirquet tuberculin test, and to Dr. G. R. Girdlestone for the facilities accorded us at the Wingfield Orthopædic Hospital. Further, to Geheimrat Prof. Dr. Kolle for kindly supplying us with the Frankfurt standard tuberculin, and to Dr. R. A. O'Brien, of the Wellcome Research Laboratories, for certain samples of tuberculin, and similarly to Prof. C. O. Jensen, of the Veterinary High School, Copenhagen. Our special thanks are due to Miss Jörgensen for the great assistance she has rendered us in the performance of the tests.

EXTENSIVE HÆMORRHAGE INTO THE PITUITARY

IN A CASE OF ENCEPHALITIS LETHARGICA.

BY L. P. DE COSTOBADIE, F.R.C.S. ENG.

With a Report on the Morbid Anatomy by

B. J. RYRIE, M.B. EDIN.,
PATHOLOGICAL DEPARTMENT, MANCHESTER UNIVERSITY.

AN autopsy on a case of encephalitis lethargica showed a condition of the pituitary gland which, we think, has not been described hitherto. On opening the skull the cerebral fluid was found to be under considerable pressure, and the pia slightly injected. When the brain had been removed, the pituitary, which was enlarged to about five times the normal size, was seen to bulge up out of the sella turcica as a soft purple-coloured tumour; the bony cavity was, however, not enlarged nor the bone eroded. The gland and mid-brain were examined microscopically by Dr. Ryrie, whose report follows. The brain showed beyond doubt that the patient was suffering from encephalitis lethargica. The pituitary showed an extensive and recent hæmorrhage into the anterior lobe. The interest of the case, we think, lies not merely in the rare glandular condition, but in its association with a new and largely unexplained disease.

The Pituitary Gland in Relation to Sleep.

Amongst the theories put forward to explain pathological sleep, and applied notably to the lethargy which is such an outstanding feature of epidemic encephalitis, that which supposes a derangement of pituitary secretion has received some attention. The work of Cushing [1] and others showed the relation between experimental hypopituitarism and sleep, and the clinical phenomenon of periods of lethargy in patients suffering from hypopituitarism. Blair Bell [2] discusses the action of the pituitary secretion in hibernating animals, with their deposition of fat and subnormal temperature. And many cases of encephalitis lethargica have shown as residua obesity, polyuria, or Fröhlich's syndrome, suggesting that the toxin may injure the gland.[3]

Acting on these facts and suggestions, the gland has been examined in a few fatal cases of this disease, but with no conclusive results. Hall [4] gives references to several cases in the literature of congestion of the pituitary, thrombosis of veins, necrosis of cells, or partial hypertrophy, but the changes were so slight that no pathological significance could be attached with any certainty to the lesion.

Apart altogether from encephalitis lethargica, hæmorrhage into the gland, unless occurring when a degenerating tumour is present, is rare; we can find only one reference. Marchand [5] described it in a case of epilepsy, but the hæmorrhage was too small to enlarge the gland. We regarded the finding of this unusual tumour, therefore, as opening up several interesting problems.

Clinical History.

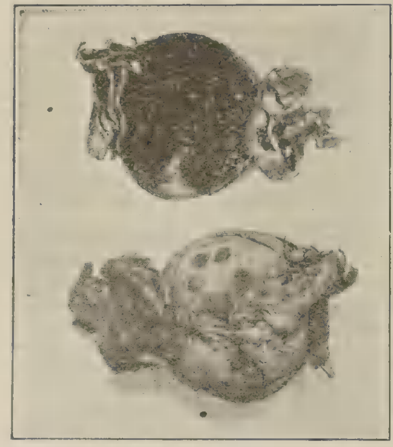
A brief summary of the case may be of interest, as it gives a striking and typical clinical picture of one form of the disease.

The patient, a man, aged 49, married and two children, was ill for a fortnight with marked insomnia, severe frontal headache, and occasional vomiting. Later he passed into a condition of restless delirium with violent choreiform movements; this alternated with profound stupor, when he would lie for hours motionless upon his back with waxy pallor, closed eyes, and mask-like face. He had the dry, furred tongue and fœtid breath usually present in severe cases. Ptosis was marked, he was at no time ever able to open his eyes. He had remission of symptoms with moments of unclouded intelligence during the four weeks before he died, also transient involvement of other cranial nerves. He had purulent conjunctivitis—I have noticed conjunctivitis of varying degrees of severity in 10 cases out of 97 that I have examined during the last epidemic. The optic discs and the visual fields were unfortunately not examined. The cerebro-spinal fluid was under increased pressure. The urine, which was not excessive, showed no sugar or other abnormality. The temperature was in the region of 101° F. for the first fortnight and then remained at 97°, rather a common feature, I think, of this disease. The pulse was unusually slow and he appeared to feel the cold unduly. The restlessness became more marked with much rigidity of the limbs, the patient became gradually weaker, and died six weeks after the onset of the disease.

The question may be asked, Is there any evidence from the previous history or from the present illness that the pituitary had been diseased for some time prior to the onset of the encephalitis? If the gland had been in a state of hyperplasia and then, as is often the case, had undergone degeneration we should expect evidence of hypopituitarism, and with a tumour as large as this, some "neighbourhood signs." There was, it is true, a vague history that during the past year headache had been complained of, and the eyesight had been deteriorating, but nothing more definite could be learned. The only suggestion that there was a deficiency of secretion was the patient's unusual hairlessness. Though pubic hair was present he had never shaved, and the skin was of that soft velvety type with much panniculus seen in cases of hypopituitarism. It is difficult to decide, therefore, on the actual cause of the glandular condition, but we think that its rarity and its occurrence in encephalitis lethargica, especially in relation to the "pituitary theory" of sleep, makes it worth while recording. Sections of brain tissue confirm the diagnosis of encephalitis lethargica.

Condition of the Pituitary.

The pituitary, after alcohol fixation, weighed 3 g. The photograph shows its actual size and there is obvious shrinkage during fixation. On section the tissue appeared as a hæmorrhagic mass except for a small pale area posteriorly. Microscopically, the entire central part of the gland is hæmorrhagic, only a narrow ring of non-hæmorrhagic gland remaining at the periphery. This peripheral part consists partly of compressed pituitary tissue and partly of apparently normal tissue, and in this zone, as in the capsule, there is blood pigment giving the iron reaction with potassium ferro-cyanide.



Hæmorrhage into pituitary body. Actual size. The upper figure shows the appearance on section.

The hæmorrhagic zone is intersected by interrupted bands of structureless tissue corresponding in distribution to the original stroma, and apparently continuous with the unaltered stroma of the peripheral part. This tissue does not stain by Weigert's fibrin stain nor by methyl-violet, but does stain irregularly by Mallory's connective-tissue stain.

Partly free in the blood, and partly in definite relation to this stroma are many persisting pituitary cells, eosinophil, and fairly well preserved. The hæmorrhage is not sharply defined from the peripheral zone, and there is no evidence of organisation. It is recent, though not terminal. The posterior lobe is not involved. There is nothing in the sections to indicate pre-existent neoplasm or other abnormality. The adjacent cerebral vessels show atheroma and extreme medial calcification.

Whether the hæmorrhage has resulted from the encephalitis or not, the histological evidence indicates that in this case it occurred during the course of that disease.

LIVER ABSCESS.

A SERIES OF SIXTY-FOUR CASES.

By E. OWEN THURSTON, F.R.C.S. Eng.,
LIEUT.-COLONEL, INDIAN MEDICAL SERVICE.

The recent papers on the subject of liver abscess by Manson-Bahr, Low, Pratt, and Gregg[1] and Neligan[2] make me think that this further series of cases may be of interest. Manson-Bahr and others, moreover, state that until recently the open operation was universally considered the correct surgical procedure. Neligan queries this, and asks: "Is not the aspiration treatment firmly established in tropical practice?" Certainly, as far as I am aware, it has been the operation of choice for at least the last ten years in Bengal; but apparently it is not so elsewhere, and I therefore wish to point out in this paper its many advantages. At the discussion of my original paper before the Medical Section of the Asiatic Society of Bengal in 1914, the chief criticism was directed upon my statement that the open operation was to all intents and purposes obsolete except under unusual conditions. As I desire here rather to prove the value of the aspiration treatment, only a short résumé of the cases is given (with remarks on those that are unusual). I have left the question of diagnosis, &c., untouched. This paper is, in fact, merely a continuation of my former one.[3] The cases which follow have all been operated on by myself, and the notes are from my own records. I mention this because hospital notes are not always as complete or exact as they might be.

Statistics of the Cases.

Of the above cases 63 were males with one female; 52 were Hindus, 11 Mahomedans, and one Britisher (my operative work since September, 1914, has dealt only with Indians). A history of dysentery was present in 44 cases, negative in 22; 29 cases were accustomed to take alcohol, 35 not. This is a large proportion, as most Indians are teetotallers. The age varied from 14 to 70, the average being between 30 and 40, but the majority of the patients were ignorant and doubtful about their exact ages. The duration of symptoms varied from five days to eight months; the former course was the most acute I have ever seen, the latter unusual, to which later reference will be made.

Of the total of 64 cases, 49 were treated by aspiration alone—in these are included three cases in which a preliminary cœliotomy was performed, as the diagnosis was doubtful; of these 40 were cured and 9 died. Four cases were aspirated, and later drained; there were no deaths. Nine cases were treated by incision, cleaning out of the abscess cavity with gauze, in some cases combined with irrigation, and the wound was then tightly sewn up in layers. In my first paper it was stated that the cases thus treated broke down later, but healing was very much hastened; in the above series it will be seen that several healed up without any complications and were rapidly cured. Again there were no deaths. Two cases were treated by incision and drainage; no deaths occurred.

The total death-rate for all methods amounts to 14 per cent. Taking the cases which were only aspirated, 28 were aspirated once, with 4 deaths; 12 were aspirated twice, with 3 deaths; 7 were aspirated three times, with 1 death; 1 four times, with a fatal result; and 1 five times, with recovery.

The largest amount of pus removed at any one aspiration was 96 oz., 3½ oz. more than my previous record, but over 100 oz. have been noted. The smallest quantity was 4 oz.; with multiple aspiration the largest amount was 220 oz. In the two cases in which drainage followed aspiration the pus amounted to 117 and 110 oz. respectively before the open operation was performed.

Rogers[4] has worked out the mortality from the open operation according to the site of the wound, giving 40·5 per cent. for the abdominal wall route and 73·4 per cent. for the chest wall route. There is something of a fallacy here, the important point being the site of the primary focus of the abscess; one, for example, deeply in the substance of the right lobe will be more difficult of diagnosis and be longer before being operated on, with greater destruction of liver tissue, than one on the anterior surface of either the right or the left lobe. This point is apparently not of so much importance with aspiration treatment. In the above nine fatal cases, four were operated on in the epigastrium, two in the nipple line in front, and only three laterally.

Summarising the figures somewhat roughly, there are 35 lateral operations and 25 epigastric, with four in abnormal positions; epigastric operations include both right and left lobe abscesses. In considering the cause of death in the fatal cases it is to be remembered that in this series all were advanced or very acute cases. In two cases there were multiple abscesses, combined in one with extensive ulceration of the bowel; two were practically moribund on admission and death occurred in a few hours; one was in bad condition and succumbed to cardiac failure ten days after operation; one was a very acute case and died in three days; and one an old man of 70, with albuminuria and glycosuria. One was a case of recurrent-abscess, with dysentery and phthisis, with death from recurring hæmoptysis. One patient was admitted with jaundice, developed pneumonia, and was probably a case of septic infection developing in an amœbic abscess before operation. Practically it almost amounts to this, that in uncomplicated cases there were no deaths.

Before proceeding to discuss treatment in detail, some unusual cases may be referred to: Case 19, an abscess pointing over the crest of the right ilium; treated by incision and suture, broke down, typical liver pus with living amœbæ discharged; the abscess was extra-peritoneal and had tracked down from the extra-peritoneal surface of the liver; Case 40, an abscess pointing in the right loin; Case 46, expectorating liver pus on admission.

Treatment.

It must be fully recognised that adequate treatment with emetine is as important as the operation. Neligan has noted the difference in comfort to the patient between the open operation and aspiration, but it may be as well to emphasise it again; on the one hand, you have the patient clothed in a mass of dressings and bandages in a moist heat which may be anything from 80° to 100° F., and on the other the patient unclothed with a scrap of cotton-wool and collodion over the aspiration puncture. Further advantages are: no frequent and often painful dressings, with risk of septic infection; the vast economy in dressings, to say nothing of time, both factors not to be neglected; and, moreover, the shortened period of the stay in hospital. In my uncomplicated cases with one aspiration it would be a week to ten days. The operative technique is remarkably simple, all that is necessary being an ordinary Potain's aspirator. General or local anæsthesia can be employed, depending upon the condition of the patient, preferably local, especially for cases in bad condition. The site of the puncture is important and should always be towards the upper surface of the abscess, particularly in epigastric cases. An abscess extending to the level of the umbilicus should be aspirated from above downwards from just below the costal margin, because as the pus is being evacuated the liver retracts upwards with great rapidity, and a puncture lower down may mean that all the pus will not be evacuated, to say nothing of the risk of breaking down adhesions and consequent escape of pus into the abdominal cavity. If an abscess is pointing, aspiration should be performed through as healthy skin as possible to prevent subsequent leakage.

I always have two bottles ready, and when one is full it is replaced by the other, so that the aspiration s practically continuous; an assistant, when the flow shows signs of weakening, uses the exhaust syringe without my closing the stop-cock on the ube attached to the cannula. If the flow is checked by the cannula becoming blocked the trocar is ntroduced again or a stylet. Every endeavour is made to empty the cavity completely, and the wall of the abscess should be searched over with the end of the cannula as the flow of pus diminishes; in this way a fresh pool may be found. When the aspiration s finished the puncture is sutured with one horsehair stitch to prevent any leakage and possible nfection, and the wound dressed with cotton-wool and compound tincture of benzoin or collodion. I wish to emphasise what I consider a most important point, which has apparently been overlooked by the writers who quote my previous paper, and that is he subcutaneous injection of emetine immediately he aspiration is finished. My practice in the last few cases has been to inject the emetine while the aspiration is going on.

The reasons for this are that with the emptying of the abscess cavity there is a negative pressure set up, and later an effusion of serum into it from outside; if, therefore, this serum can be charged with emetine it will be able to attack the living amœbæ in the outer wall of the abscess, which it is most important to destroy. The amount of emetine employed was at first gr. 1, later increased to gr. 1½, and now gr. 2 are always given. Emetine was given in all but seven cases, the average total amount being gr. 5·7, unless the patient was in a very bad condition. I consider that the injection of quinine or emetine into the abscess cavity is of no value except in so far that the emetine may later be absorbed, and it is preferable to give it hypodermically. In cases which require further aspiration emetine is administered in the same way.

Cases Treated by Other Methods.

In the above series of cases it will be seen that 15 were treated by other methods, and it is necessary to explain the reason. First, there were four aspirated and subsequently drained. Case 26 was aspirated five times by myself, then handed over to a colleague when I went on service, and drained by him. Case 35 was obviously septic on aspiration. Case 49 had nine aspirations, then infection through puncture. In Case 57 aspiration was unsatisfactory—epigastric abscess; I incised small cavity on the surface of the liver; hæmorrhage, gauze packing; if there had been no hæmorrhage the wound would have been sutured.

Secondly, two cases were incised and drained at once. Case 30, a doubtful swelling; the liver exposed and aspirated, no pus; recent adhesions broken down; abscess largely subdiaphragmatic; risk of peritoneal infection, hence drained. Case 40, skin adherent and inflamed; wound of attempted operation by village practitioner; sepsis.

Thirdly, nine cases were treated by incision, cleaning out the cavity with gauze and primary suture. This operation was first performed by myself over 12 years ago, and is a very useful procedure, particularly in those cases in which the diagnosis is doubtful or the swelling is in an abnormal position. A fairly common class of case is one in which there is an indefinite swelling in the epigastrium with a doubtful history, and to plunge an aspirator needle into this swelling on the off-chance of its being a liver abscess would be very unsound surgically. This operation covers the difficulty; in fact, in some cases I am inclined to believe it is the operation of choice. One point about it is that the possibility of infection through a drainage-tube is avoided, and there are no frequent dressings. Cases 14, 19, 27, 33, 34, 35, 43, 48, and 60 were thus treated; seven were of doubtful diagnosis and two in abnormal positions; seven healed by first intention, only two of which later broke down.

Manson-Bahr and others lay stress on the importance of a course of emetine-bismuth-iodide after operation. I have not been able to give this, chiefly on account of the financial condition of the hospitals of which I have been in charge, and, moreover, native patients rarely stop in hospital after they consider themselves cured. As regards the amount of emetine, gr. v. to x. should be ample. I consider the amount of emetine administered is often too great; speaking generally it acts as a specific or not at all, and I am certain that giving a big dose during the aspiration is most important. If an abscess has once formed emetine will limit its extension and quiet down symptoms, but not cure it; if there is suspicion of an abscess it is better to aspirate to be on the safe side. Case 33 was an example of the failure of emetine.

Considering that the total mortality of this series of unpicked cases in natives is only just over 14 per cent., I see no reason why it should be more than 5 per cent. in early uncomplicated cases with adequate treatment.

It may be of interest to quote the cases in my first paper treated by aspiration alone. They were 50 in number, with 38 recoveries and 12 deaths; the earlier cases were treated with ipecacuanha, the latter with emetine, but not so efficiently as is done now. Combining the two sets of figures: of 99 cases, 78 were cured, equalling 77·7 per cent., and 21 deaths, mortality-rate 22·3 per cent. Compare these with Rogers's figures of the open operation, giving a mortality of nearly 60 per cent.

Summary.

To conclude, aspiration combined with hypodermic exhibition of a large dose of emetine *at the time* is the operation of choice.

In cases of doubtful diagnosis, explore and either aspirate or clean out the cavity and suture the wound firmly. Emetine should be given at the same time. Drain only as a last resource, the sole indication being sepsis.

Clinical and Laboratory Notes.

TWO CASES OF EARLY AND LATE ANAPHYLACTIC PHENOMENA

AFTER ADMINISTRATION OF DIPHTHERIA ANTITOXIN.

By Norman S. R. Lorraine, M.D. Edin., D.P.H. Edin. & Glasg.,
RESIDENT MEDICAL OFFICER, CITY HOSPITAL, HULL.

In view of the apparent rarity of true anaphylactic phenomena, it may be of interest to mention two instances of what would appear to be definite cases illustrating the peculiar reaction which may result from the injection of serum, the sequelæ being alarming, but fortunately not fatal.

Case 1.—Girl, aged 12½ years, admitted to City Hospital, Hull, suffering from a moderately severe attack of diphtheria. The history indicated that she was in the third day of the disease, with the usual onset. Membrane was present on both tonsils, right posterior faucial pillar, left side of uvula, and extending on to soft palate. Glands of neck on both sides much enlarged. Heart sounds normal. Throat culture definitely positive.

Shortly after admission the girl received an injection of 10,000 units of antidiphtheritic serum subcutaneously in the lower part of the abdomen. Within about five minutes of this injection a well-marked blotchy urticarial erythema appeared, involving the face, body, and extremities almost simultaneously. The œdema of the upper and lower eyelids was intense, and prevented opening of the eyes. The patient was obviously in distress, and the pulse at the wrist became practically imperceptible. She placed her hand over the heart and indicated cardiac embarrassment. The bed was tipped, brandy was administered by mouth, and hypodermic strychnine, gr. 1/60, was given without immediate improvement. The patient throughout was able to speak rationally and without effort. The heart sounds became very faint and the first sound in the mitral area was just audible. No increase or diminution of pulse-rate was noticed. The rash varied, as time went on, in intensity and colour, especially on the face and extremities, more particularly the former.

After about two hours the heart commenced to improve, although the pulse was very thready, soft, and of poor quality, but countable. Within four hours the rash commenced to fade, more particularly on the body, and the œdema of the eyelids became gradually less. At the same time the pulse showed an improvement. Within ten hours of the commencement of these phenomena the rash had completely disappeared without staining, and the patient appeared comfortable, the pulse being definitely improved.

It would appear that this patient had 8000 units of antitoxin one year nine months previous to the above-mentioned injection of serum for diphtheria without any ill-effects. No indications whatever existed of asthma.

The patient had an uninterrupted recovery with no complications and was discharged from hospital within 11 weeks.

Case 2.—Nurse, aged 24 years, was admitted to City Hospital on May 6th, 1924, suffering from diphtheria. She would appear to have been ill for 24 hours. Membrane was present on the right tonsil as an early and slight deposit. Culture from the throat was definitely positive. She received a sensitising dose without ill-effects, and 6000 units of A.D.S. at 11.30 A.M. The following morning she had an extension of membrane from the right tonsil on to the soft palate and right posterior faucial pillar. Membrane also present on the left tonsil, patchy, and very slightly adherent. The uvula was free. An additional 6000 units were injected. At 10.30 P.M. on May 10th she gradually changed colour and complained of nausea. She retched but did not vomit. The pulse at the wrist became poor and almost uncountable, and she developed a faint serum rash without elevation of temperature or joint pains. Her colour was very poor and rather characteristic of early cardiac paralysis in a case of diphtheria. On examination of the heart the sounds were regular but diminished. She received brandy and cardiac stimulants hypodermically, to which she did not react for an hour or two. Serum rash, although scanty, lasted for 72 hours.

She had an uninterrupted recovery and was discharged from hospital within 11 weeks. Throughout her illness there was no albuminuria, and it would appear, in view of the facts that she received serum early, that her throat was mildly affected, that she had received 8000 units A.D.S. seven months previously for diphtheria, that the cause of sudden change was more likely to be associated with anaphylaxis than early diphtheritic cardiac paralysis. In type she was adipose and unhealthy, showed no evidence of asthma, and states that she has no recollection whatsoever either of her temporary embarrassment or of the treatment she received during this somewhat alarming experience.

In both these cases the clinical symptoms appeared so severe that I felt justified in notifying the respective relations. I may add that the serum employed in both these cases was standard A.D.S., manufactured by a firm of repute.

I am indebted to Dr. J. Wright Mason, medical officer of health, Hull, for his kind permission to publish these records.

A CASE OF POISONING BY "VAPO-CRESOLENE."

By Edward G. Gibbs-Smith, M.D. Durh., D.P.H.,
MEDICAL OFFICER OF HEALTH FOR TEDDINGTON.

The following case of poisoning by the accidental drinking of "vapo-cresolene" may be of interest on account of its rarity, as I have been unable to find a similar case in medical records. Vapo-cresolene is a well-known American preparation which has a large sale in this country, and is commonly used as a remedy for whooping-cough. It is put up in a specially made square indented bottle so that it can be recognised in the dark. Directions are printed on the label telling what antidotes to take in case the preparation is taken internally by mistake.

Messrs. Allen and Hanburys are the British distributors, and they have kindly provided me with the following description of cresolene: "Vapo-cresolene consists practically entirely of a mixture of free creosols or cresylic acids. These, of course, are members of the phenol group, and vapo-cresolene may therefore be considered to consist practically entirely of phenols, although it contains only a very small amount, if any, of actual phenol (carbolic acid)."

The patient, a healthy woman, 28 years of age, drank from a bottle about two teaspoonfuls of vapo-cresolene in mistake for cough mixture. She immediately went for help, drank a tumbler of water, and within five minutes became unconscious. I saw her 15 to 20 minutes after she took the poison. Her face was pale and puffy; very slight cyanosis; lips burnt and swollen; slight discoloration on the chin; fauces were burnt on both sides, the burnt patches extending down as far as could be seen. The breathing was regular but somewhat hampered by a large amount of secretion; pulse 120–130, fairly good; skin rather cold but not moist; temperature subnormal (97° F.); pupils slightly contracted. The poison was taken at about 12.30 A.M. on Oct. 4th. At about 1 o'clock the following treatment was commenced: Alcohol by the mouth, strychnine 1/60 hypodermically, sulphate of soda, and olive oil. She remained unconscious, with periods of delirium, and treatment had to be administered by force. At 4.30 A.M. her general condition became worse, the skin was cold and moist, and signs of collapse were apparent. 7–8 c.cm. of brandy were then injected between the scapulæ; within ten minutes of this she rapidly regained consciousness and was able to say exactly how the accident happened. At this stage she complained of burning and soreness of mouth and throat, giddiness, and general weakness. More olive oil and solution of sulphate of soda were given, and a little later she vomited a considerable amount of partly digested food, oil, &c., which smelt strongly of cresolene. A fair quantity of urine was also passed, almost black in colour. There was constant coughing, and after 24 hours sloughs began to come away in considerable quantity and continued to do so in diminishing amounts for three days, after which mucus only was expectorated. During this period the temperature rose to 100·6° on one occasion.

Further treatment consisted of spraying and gargling with dilute glycothymoline, and swallowing slowly dilute bovinine. The latter was given as an application to the damaged tissues as well as for nourishment. When the sloughs had finished coming away an examination with the laryngoscope showed no inflammation of the vocal cords, but the surrounding parts were somewhat congested, and small quantities of mucus were adherent in places.

The case presented no signs of œdema of the glottis or other serious complications. By the ninth day the patient had made a good recovery and was able to leave home.

I append the analyses of two samples of urine, kindly made for me by Messrs. Allen and Hanburys.

(1) Sample of urine passed at 5 A.M. Oct. 4th, 1924: Colour and appearance, bluish-violet containing some suspended matter. Reaction, alkaline; sp. gr., 1036; albumin, distinct trace; sugar, absent. The sample affords distinct evidence of the presence of a phenol, and the bluish-violet coloration appears to be due to the presence of indoxylsulphonic acid, due probably to the ingestion of a phenol. The presence of pyrocatechol and hydroquinone is also indicated. The deposit consists of some quantity of epithelial debris and numerous crystals of triple phosphate.

(2) Sample of urine passed about 6 P.M. Oct. 5th: Colour and appearance, greenish-brown, turbid; reaction, alkaline; sp. gr., 1039; albumin, distinct trace; sugar, absent. The sample yields no indication of the presence of a phenol and gave no reaction for indoxylsulphonic acid. The deposit consists of amorphous urates, numerous crystals of triple phosphate, and some epithelial cells.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF OBSTETRICS AND GYNÆCOLOGY, EPIDEMIOLOGY AND STATE MEDICINE, AND THE SOCIETY OF MEDICAL OFFICERS OF HEALTH.

NOTIFICATION OF PUERPERAL SEPSIS.

A SPECIAL combined meeting was held under the presidency of Dr. RUSSELL ANDREWS, on Nov. 6th, of two sections of the Royal Society of Medicine jointly with the Society of Medical Officers of Health. The meeting was called in the following circumstances.

Sir George Newman, in May, 1924, addressed a letter to the Section of Obstetrics and Gynæcology of the Royal Society of Medicine, stating that the Minister of Health, after consideration of a report on maternal mortality recently issued by the Ministry, was anxious to take such steps as possible to reduce the incidence of maternal mortality and particularly of puerperal sepsis, and he therefore asked for observations from the Section as to the administrative action which might suitably be taken in this matter "especially with regard to the terminology and definition of puerperal fever . . . . as may lead to the prompt notification of the occurrence of this morbid process as soon as symptoms suggestive of septic infection become manifest, that adequate nursing and treatment may be ensured. . . ."

The Council of the Obstetrical Section referred the matter to a subcommittee consisting of Dr. Russell Andrews, Sir Ewen Maclean, Mr. Aleck Bourne, and Dame Janet Campbell. This subcommittee's suggestions were brought before the Council of the Obstetrical Section on July 3rd, and the question of the actual wording was left in the hands of Dr. J. S. Fairbairn, Dr. H. Williamson, and Dr. Russell Andrews. They reported as follows to Sir George Newman:

"Any case in which there is a rigor or a temperature of 102° or higher for 24 hours, during the first ten days after confinement or abortion, must be notified.

"Get rid of the official term 'puerperal fever' and use in its place the term 'puerperal sepsis.'

"Puerperal sepsis is a febrile condition of the nature of wound infection, arising after labour or abortion, due to bacterial invasion from, or absorption of, products of bacterial action from some portion of the genital tract,"

nd asked him to make further suggestions on their report. Sir George Newman later pointed out how important the matter was, as it might influence future legislation, and, fter discussion at a further Council meeting, it was thought better to submit the matter to a meeting of the whole Section, nd at the same time obtain the views of the Section of Epidemiology and State Medicine and the Society of Medical Officers of Health.

Dr. J. S. FAIRBAIRN opened the discussion. He aid: To compress what I have to say within the mits allowed, I will confine my remarks almost ntirely to two points—(1) What should be notified nd (2) the pros and cons of notification. There will probably be a divergence of opinion in this meeting regarding the definition of what should be notified equal to that among the members of the subcommittee—i.e., as many opinions as individuals present. Support will surely be found, however, for the general principle that notification is useless unless the early and suspicious cases are included as well as those of undoubted puerperal sepsis. The Scottish Departmental Committee considered the matter, but feared to make any definite recommendation. The one suggested by the subcommittee to include early and suspect cases is before you—"Rigor or temperature of 102° or over for 24 hours"; it was the shortest and most comprehensive that could be arrived at; if anyone here thinks he can devise a better, let him submit his effort to the meeting to see if it meets with a wider acceptance.

For my own part I have found it helpful, and perhaps others may find so too, to bear in mind the type of case that we would consider a danger to nurse in a ward with other lying-in patients and the usual hospital procedure in dealing with it. True, the risk of contagion to others is very much less when the patients are already isolated in their own homes, though there is even there the risk of conveyance of infection to others by doctors, midwives, and maternity nurses; moreover, notification concerns also patients delivered in nursing homes and maternity hospitals of all sorts and kinds. In domiciliary practice, nursing homes, and in many of the small maternity homes that have sprung up of late, there are not the facilities for the thorough investigation of suspect cases that a big hospital offers, so that the greater delay in reaching a definite diagnosis may be set off against the lesser risk of spread.

In other words, we shall not be far out if we take as our guide the conditions that might be regarded as necessitating isolation and special investigation if they occurred in a patient in a lying-in ward. Though many of the cases coming under the suggested definition will turn out to be infections of the urinary tract or other non-genital area, and in many of the remainder the fever will subside rapidly without further complication, I think most of my obstetric colleagues would agree that they would have all such cases forthwith moved into the observation ward; delay is not worth the risk involved.

In case this method of putting it may not appeal to all, I will set the argument out in another way. Notification only comes in when our first line of defence—prevention—has been breached; the next line to be held is that of catching the disease early and scotching it, and that is only possible if the suspicious cases are included. Treatment is likely to be most effective in the early stages, and if notification is to be preventive of further spread, a trifling and transient pyrexia, which may be the start of an outbreak of more serious infection, should not be excluded.

I take it that I am justified is assuming that I have now put the case for the notification of suspect cases so clearly that the meeting is with me and that the only problem left to it is merely that of framing a better definition than the one suggested.

Notification to Include Suspicious Cases.

I will therefore proceed to the next point, the discussion of what can be said for and against a notification of puerperal sepsis wide enough to include the suspicious cases as well as those definitely diagnosed as such. In a characteristic obiter dictum, Prof. E. W. Fothergill has remarked on the curious fascination notification possesses for some minds. The best way to escape being fascinated by it is to look on it as a means to an end—and that end, the reduction of septic death-rate in child-bed—and to consider how it may be made to lead up to that end. The administrative action that must follow the receipt of a notification falls into two categories, according as it concerns the individual case notified and as it concerns the public. In the first category come the measures for determining the nature of the infection, the nursing and treatment of the patient, and in the second those for tracing the cause of the infection, preventing its spread, and collating the results obtained.

When the patient can afford such special services as a second medical opinion (which should be one with obstetric experience), bacteriological investigation, and adequate nursing, the duty of the health officials will be to satisfy themselves that such facilities have been made use of, and to be informed of any other particulars they may require, such as the results of examination and treatment. If, on the other hand, from local conditions or the economic position of the patient, full investigation is not possible, then arrangements should be made to provide these services, and, so far as can be, the policy should be to encourage and develop such local provision as is already in existence, both in the case of those able to pay and those who are not. The creation of new officials, without regard to the interests of those already trying to provide such services, whether private practitioners or voluntary hospitals, will in the long run be detrimental to the best interests of the maternity service as a whole.

By this means the cases notified as suspect will be narrowed down to those of true genital infection calling for special management and precautions to prevent its being carried to others. The care of the individual patient must, however, be kept in the foreground, and the measures for the public health and for obtaining information regarding causation made as little obtrusive as possible. Thus special medical advice, nursing or removal to hospital, or other provision clearly to the benefit of the patient must be the chief consequence of notification. Though removal to hospital cannot be compelled, it must be urged whenever the chances of the patient will be increased thereby, and if proper provision for the removal and reception of the patient is made, its benefits will soon be generally recognised and little persuasion needed.

Provision for those patients requiring, but hitherto unable to obtain, special investigation and treatment and the measures taken to limit conveyance of infection will be acknowledged as all to the good. Also if notification can be made to lead to an increased knowledge of the disease, it will with equal certainty lead to its lessened incidence, and hence information collected in this way from areas in which success has or has not been attained, and of the factors underlying such success or failure, is bound to be of value. I would emphasise this side as possibly the one that is likely to be most fruitful in the prevention of puerperal sepsis.

The Limitations of Notification.

But doubt must arise in the minds of many whether the notification of all suspicious cases is a possibility, and, if even it were, whether it will make much impression on the incidence of the disease. In vast numbers of confinements temperatures are not taken and recorded properly, and whatever standard is adopted there are numbers of mild infections which will escape notification and yet may develop into serious infections or be a danger to others. Foul venereal warts, vulval ulceration or vaginal discharge may cause unexpectedly little disturbance to the affected patient during her lying-in, but be virulently infective to others, and, indeed, septic conditions of all kinds in man, woman, or child may be the starting-point of genital infections in child-bed, so why single out only the puerperal infections? In all infections it is the carriers, the ambulatory and unrecognised cases that are the greatest danger, and one has only to recall both the puerperal cases that would escape notice and the causes other than puerperal infections that may be the starting-point of an outbreak to realise the limitations of notification.

Casting the net widely will certainly make the life of the practitioner who does much midwifery so much more of a nightmare than it now is that only the most thick-skinned will survive and many will be driven to give up a side of their work that is already a heavy burden. Patients and their households are not altruistic enough to take into account the lessening of risk to others and the value of increased knowledge, if attained by worry and inconvenience to themselves, and sullen opposition and resentment at official inquisition may more than counter-balance any problematical gain. Resentment will be aggravated if such further administrative action is taken as that suggested both in the Ministry of Health report and in the Scottish Committee's report—viz., that all deaths in child-bed should be inquired into or that post-mortem examinations should be made in all cases; this has been urged in some of the public discussions arising out of the publication of these reports. One form of notification that has also been put forward is much more reasonable as affording useful information in tracing the cause of infection, with no fresh formality; it is that of the addition to the birth notification form of the name and qualifications of the persons actually present at, and responsible for, the delivery of the woman.

Help for the Practitioner: Voluntary Notification.

Before concluding I would like to ask the views of our public health colleagues on the following suggestion. The immediate notification of suspect cases is obviously out of the question; it would probably involve some amendment of the Notification Acts, and certainly some years must elapse before the machinery for carrying out the measures that should follow notification can be set up throughout the country. I would ask them if it is not possible to organise, in some areas at any rate, obstetric consultations, bacteriological examinations, domiciliary nursing, and, if possible, a certain amount of hospital accommodation, both for observation and for nursing and treatment. As soon as the most essential parts of the machinery can be put together, the practitioners in the area could be informed and asked to notify voluntarily all cases of fever in child-bed; the general adoption and success of this form of notification, especially for those patients in need of public assistance, would be proportionate to its efficiency and to the advantages it offered to patient and practitioner being readily recognised. In this way less time would be lost and much valuable experience gained, both by the practising and administrative sides of the profession. The report of the Scottish Departmental Committee makes this suggestion (par. 102) both in connexion with notification and the investigation of deaths within a month of the termination of pregnancy, and states that a form of voluntary coöperation has already been worked in Aberdeen and elsewhere.

The reports recently published and Circular 517 of the Ministry of Health show the necessity for action—a need long recognised by this Section as reference to its Proceedings will show—and both the Ministry and the local authorities are being urged to take action. Let us hope it will not be precipitate action, but considered action taken, if possible, after the possibilities have been explored by local effort, in some such way as I have suggested.

Dr. R. **DUDFIELD** considered that the reason that notification was so unsatisfactory was because the definition of puerperal fever was so indefinite. He personally would like to see the term puerperal fever kept for purposes of notification, since it is the term in use in other countries and, moreover, the public know what it means. He would like to see the profession in a position to certify suspect cases. He agreed with Dr. Fairbairn that closer coöperation between public health departments and private practitioners would be desirable, and he did not think the scheme outlined by Dr. Fairbairn would be at all impracticable. Dr. Dudfield made two constructive suggestions: (1) That the law should be altered to allow a practitioner to notify his suspicion that his patient has puerperal fever, thus obviating any delay while waiting for a certain diagnosis; and (2) that some public body, such as the Ministry of Health or the Medical Research Council, should appoint a small committee of experts to collect and digest information relating to notified cases. Such a committee could formulate a questionnaire which could be circulated to medical officers of health and through them to practitioners. Practitioners should be offered an adequate fee for filling it up, and the expert committee would then be in a position to investigate the notes made by practitioners in a convenient and uniform order. All inquiries could be made in writing to the M.O.H., and from the data collected some lines of dealing with the disease might be worked out. The cost would, of course, be considerable, but it was highly probable that such a committee would not require to function for many years if the profession generally coöperated heartily. To show how unsatisfactory was notification under present conditions, Dr. Dudfield quoted an estimate by W. E. Fothergill of the proportion of cases escaping notification in 1920. Fothergill estimated that in that year there must have been 70,000 to 80,000 cases in England and Wales; the cases notified during the year numbered 2898, rather more than 4 per cent. of the lower estimate (70,000).

The Need for Better Supervision of the Midwife.

Dr. R. A. **LYSTER** said that investigations into the possible causes of maternal mortality always led to one result—namely, that the chief and almost sole cause was bad midwifery practice. Experience in the supervision of midwives for the past 20 years had convinced him that the level of midwifery practice could be substantially raised by efficient supervision and inspection. The Midwives Act was obviously intended to create a body of midwives practising under close supervision and inspection, but that intention had never been carried out. Midwives exercised considerable influence through their societies and they control to some extent the Central Midwives Board. By means of this influence they had successfully prevented the organisation of schemes whereby their work could be properly checked and supervised. The unfortunate result was that 20 years working of the Midwives Act had resulted in little or no improvements in mortality connected with midwifery or mortality among newly-born infants. As an illustration of the manner in which notifications could be made entirely ineffective he referred to the working of the Notification of Births Act, 1907. Although midwives had to notify the birth within 36 hours, yet no official visits were paid by health visitors to that house during the first ten days. It was the mortality among mother and infants during these ten days that had shown so small a diminution during the past 20 years, and Dr. Lyster had no doubt that merely by the introduction of regular visits by health visitors immediately after the notification of the birth has been received a very striking improvement would result. In practice, the payment of subsidies to midwives in sparsely populated districts was found to be unreasonably costly when the total cost was compared with the number of confinements attended. It was far cheaper and more satisfactory to provide maternity homes. Maternal mortality would, of course, be substantially and immediately reduced by the provision of maternity beds for complicated cases, and for those cases whose home conditions are unsuitable. To these he would add the cases occurring in sparsely populated districts. Notification, unless it could be accompanied by substantial schemes of practical utility, was worthless from a preventive point of view. In his own area the notified cases of puerperal fever fell short of the deaths from that disease. The practical way to bring the practitioner into prevention was to start by paying him a fair fee for a full report on these cases. The proposals now being made in the way of amendments of definition and regulations for notification were quite sound and would be useful, but only if we could arrange a definite scheme of dealing practically with these notifications. The obvious course was for the notification to be followed by an offer of assistance of various kinds. If the case could be nursed at home, then an offer of skilled nursing assistance should be the immediate result of the notification. If operative treatment was necessary, then an institution must be at once available for the case, or in cases that might be treated at home the services of a consultant should be forthcoming on the request of the practitioner concerned. Last, and not least, there was the question of the supply of nourishment to such cases, altogether apart from the general question of such provision to expectant and nursing mothers.

A Royal Commission?

Dr. T. W. **EDEN** observed that reference had been made by several speakers to the fact that notification as at present carried out was unsatisfactory; this was the salient fact to be considered. Why was it that the present system had so completely broken down? There were good reasons. The two questions which the practitioner asked himself were (1) Is it a case of puerperal fever? and (2) Need I notify it? The first question was one of honest doubt and the second was caused by a desire to call it by any other name if he possibly could, because it was fixed in the public mind that if the case was indeed infected he was to blame. Thus, the practitioner's attitude with regard to notification of this disease was quite different from his attitude with regard to notification of other diseases. Now it was obvious that without the willing coöperation of the practitioner any scheme would break down. It was, in Dr. Eden's opinion, a mistake to approach the subject from the aspect of notification. At the earliest stage the whole field of puerperal morbidity must be brought into view. Would it not be possible to organise a system of puerperal observation wards to which practitioners could be encouraged to send all cases which seemed to be going wrong? In that case the odium of notification would be taken off the doctor's shoulders. Liberal State assistance would, of course, be required. Dr. Herbert Williamson, who was unfortunately unable to be present that evening, had suggested that the subject was worthy of a Royal Commission, but even if this were not considered possible, some committee of investigation should be set up. Some form of national midwifery service was essential. It was difficult for the Ministry of Health to keep in touch with the practical needs, but if the subject could be approached as a whole by a committee composed of both medical and lay members, some broad scheme might be worked out to meet requirements.

Needs of the Practitioner.

Dr. C. E. S. **FLEMMING** pointed out that notification was only a part, and by no means the most important part, of the process of prevention. The replacement of the term puerperal fever by that of puerperal sepsis was a practical step from the practitioner's point of view, since there were certain febrile conditions not due to sepsis—for example, influenza; the diagnosis and selection of cases for notification must be left to the practitioner. He would doubtless be grateful for a second opinion at an early stage; it might be difficult, however, to find a sufficient number of experts. The quarter in which notification had to be made was another point requiring consideration; in some cases a practitioner now had to notify to an M.O.H., who was his rival in practice. Dr. Flemming quoted a case where a patient of a certain practitioner went septic; he found, subsequently, that the district nurse who attended this patient was also nursing two infected puerperal cases, both being patients of the M.O.H. of the district. It should be the duty of M.O.H.'s to inform the midwife and the nurse in attendance when any case had been notified as septic. Notification had only a limited use in preventing infection. If mild cases of sepsis which were likely to recover were notified there would be a further advantage, in that the opprobrium attached to a case which did well was much less than that attached to a fatal case. Moreover, medical men doing antenatal work should have the power, or even the duty, of notifying those antenatal cases which were in unsuitable surroundings, and some provision should be made for the removal of these patients into proper conditions. Notification was useless if there was nowhere to send the patients; the isolation hospital was now the only place where they could be sent, but it was essential that someone should be there capable of looking after them.

Dr. W. BUTLER said that puerperal sepsis, its origin and prevention, its clinical and pathological identity fell within the sphere of action of preventive medicine as surely as did small-pox or scarlet fever. To attain this object, divergent interests must first, as far as possible, be reconciled. To this end he suggested a broader basis for notification and at the same time a definite specification of the clinical phenomena it is sought to embrace under the statutory obligation. The suggestion of the subcommittee of the Obstetrical Section was precise and met these requirements. But obviously, and even fortunately, there was embraced in this definition a variety of conditions which it would be incorrect and misleading to describe as puerperal sepsis. He suggested sustained puerperal pyrexia as a suitable condition for notification to the medical officer of health.

Dr. HAROLD SCURFIELD noted that all speakers agreed that notification had been a failure. There seemed to be an impression among practitioners that sepsis following a miscarriage need not be notified. He agreed on the importance of working out a scheme for dealing with cases before the details of notification were discussed. Tuberculosis was not notified so well as some people appeared to think; indeed, in all diseases notification appeared to vary with the efficiency of administrative measures for giving help to the practitioner. At Sheffield when he was M.O.H. there, the only resource for cases of puerperal fever was the Poor-law hospital. He agreed that any suggestions made should be coupled with a strong recommendation that a well-thought-out and comprehensive administrative scheme should be got out.

A Plea for the Midwife.

Dr. MARY KIDD put in a plea for the midwife, who was very badly paid and worked against heavy odds; could she perhaps be provided with an allowance for rubber gloves and perhaps also with a sterilised outfit by the local authority? Many mothers would much resent the intrusion of a health visitor on the second or third day after delivery, especially if her visit involved some asperities between her and the midwife. Inspection by health visitors would be rather hard on midwives since the former were often untrained. Women would be more willing to go to the Poor-law hospitals if only the relieving officer did not have to be interviewed; this formed a difficulty which surely might be swept away.

Sir EWEN MACLEAN said that the consultative council of the Welsh Board of Health had investigated the conditions of puerperal mortality in Wales, where there were 5·41 deaths per 1000 births against 4·11 per 1000 of the general population of this country. The facts which emerged from this investigation would be the subject of a report by the Ministry of Health. In Wales notification was very little practised. Directly, or by implication, blame had been laid on the practitioner and on the midwife for omission to notify, but the real reason why notification was not carried out was the complacency of the public. The patient often raised objections to notification, or at least was quite callous as to whether it was done or not. Notification, indeed, brought no help to her. If it became known that notification resulted in benefits, prejudice would soon be swept away.

Prof. LOUISE McILROY suggested three reasons for the failure to notify: (1) It brought the practitioner into disgrace and therefore required courage; (2) it was difficult to notify puerperal fever, because it was difficult to recognise it; (3) no adequate treatment was given when notification had taken place. In fever hospitals the patient was often put under the care of a junior medical officer, and might indeed even be curetted on admission. A large hospital in the London area devoted exclusively to these cases and staffed by experts might help. The provision of post-graduate courses for practitioners was desirable.

Increased Incidence after the War.

Dr. T. H. C. STEVENSON said that from Dr. Lyster's remarks it would have seemed that 100 per cent. of the cases of puerperal fever occurred in patients under the care of midwives. It would surely be a matter of practical utility to ascertain the proportion of cases occurring in the practice of medical men. Immediately after the war, when presumably the cases attended by midwives alone must have diminished and those attended by practitioners increased, the change in condition was accompanied by a sudden and considerable rise in puerperal fever. Dr. Stevenson did not draw any conclusion from the circumstance, but wished to call the attention of the meeting thereto. The term puerperal fever had been replaced in the classification of the Registrar-General by that of puerperal sepsis, owing to the general feeling that this should be done. As to the number of different conditions tabulated under that heading, the number of conditions tabulated merely represented the different forms in which practitioners notified cases of this description.

Dr. E. W. GOODALL, replying to Prof. McIlroy, deprecated the suggestion that in fever hospitals cases of puerperal fever were put in charge of inexperienced officers; these cases were desperately bad, as a rule, when admitted, and had very little chance. Invariably it was the most experienced officer available who had charge of them, and expert opinion could be obtained when required. Since very few cases were admitted, however, it might be an advantage if they were concentrated in one hospital.

Dr. J. ROBERTSON said that in his area (Birmingham) there was a ward sanctioned by the Ministry of Health for cases of puerperal fever, so there was room for any case that might occur. The results were not so good as might have been anticipated, since cases were sent up so late that it was impossible for the best specialist to help them. The whole question of obstetrics needed reviewing; it must be remembered that the chief duty was to prevent and not to treat these cases.

Dr. REMINGTON HOBBS urged his conviction that every case of puerperal fever was a surgical case and susceptible to surgical treatment.

The PRESIDENT considered that the discussion had been very useful. It now remained for the subcommittee to meet and to consider the reply to be sent to the Ministry of Health. It could be anticipated that there would be a demand for a comprehensive inquiry.

MEDICAL SOCIETY OF LONDON.

ENCEPHALITIS LETHARGICA.

AT a meeting of this Society held on Nov. 10th, Dr. E. M. CALLENDER, the President, being in the chair, a discussion was held on Encephalitis Lethargica.

Dr. E. FARQUHAR BUZZARD, in introducing the subject, reminded Fellows that six years ago, when he read a paper before the society on the disease, he referred to it as a stray visitor, whose stay might be expected to be of but short duration. But, on the contrary, it had not only outstayed its welcome, but its incidence had so increased as to constitute a menace to the health of the community. It was humiliating to professional pride to have to confess that there was not yet available the knowledge necessary to enable its progress to be checked, though admittedly its microbic origin had been fairly determined and its morbid anatomy and clinical features studied; but we have yet to learn its path of approach and its methods of dissemination. In this contribution Dr. Buzzard specially directed attention to one or two questions which were difficult to answer and which had important bearings. There were no real characteristic symptoms or physical signs by which the disease could be recognised, and as any function of the brain might be disturbed, there might be a whole series of clinical manifestations.

Importance of History of Onset.—The diagnosis depended on a careful consideration of the history of onset and the course of events, as well as on the exclusion of other morbid processes capable of producing like disturbances. No serum or chemical test was available, and no cytological picture was pathognomonic.

Importance of the Ambulatory Form.—The acute disease did not present nearly so serious a problem as the ambulatory form, the importance of which was becoming more and more evident. He knew many examples in which serious disturbances of the nervous system had followed what seemed to be a minor illness—probably diagnosed first as influenza, or even catarrh—and he narrated two or three examples in which there seemed to have been present at the early stages nothing to enable a serious condition to be recognised. The most common early indication that a case might turn out to be ambulatory encephalitis was a transient diplopia, lasting a few days, possibly only a few hours. Another of these indications was the occurrence of acute pain in a limb or in the face or neck, regarded at the time as neuralgia. The period of diplopia might be synchronous with a definite change in temperament, in the direction of a morose restlessness. There was often a real difficulty in differentiating this disease from disseminated sclerosis.

Prognosis.

There were a number of points in connexion with late developments which had a direct bearing on prognosis. In the first week or two of the disease he would be a bold man who forecasted the behaviour of a case. The possibilities for the patient could be summarised in the following way: (1) Recovery might occur within a reasonable time and no ill-effects remain; (2) death might occur in the acute stage; (3) continuance of life might be at the cost of permanent disablement; (4) recovery might apparently ensue, but might be followed in weeks or months by relapse; (5) there might be more or less complete recovery, and then, after a variable interval, a slowly progressive sequel might develop.

In the attempt to forecast the issue certain points might be helpful. For example, the more acute the onset and the more fulminant the symptoms, especially if associated with a high temperature, the more was a speedy death likely. But, conversely, it could not be said that milder initial stages rendered less liable progressive disablement, or even an eventual fatality. Still, many cases which were of mild onset made a good recovery.

One of the interesting questions was as to whether late developments could be regarded as true relapses of a process which for a time had ceased to be active, or were cases of fresh infection. He had seen cases in which both seemed to be true, and he did not feel able to give any guidance on this aspect of the subject. Some of these cases he narrated. He also discussed the prospects of a patient who, after all other symptoms of the disease had disappeared, still had myoclonic contractions. A medical man who had an acute attack in 1916 still had myoclonic contractions in his trunk muscles in 1920, though three years later they had practically ceased, only reappearing when he was very fatigued. The speaker did not hesitate to recommend him as a first-class "life," as he was convinced that the continuance of these contractions alone did not justify a serious outlook.

Fresh Light on Cerebral Localisation.

Dr. Buzzard thought the sequelæ of the disease merited a close study because of the light they might shed on the localisation of cerebral function. One patient who had the post-encephalitic Parkinsonian syndrome said that in addition to the drowsiness and slowness of action she had fits of uncontrollable yawning, and attacks of what she described as shortness of breath, which inquiry showed were periods when she had to breathe consciously, and the same concentration was required even to sip her tea; this became a noisy process. She also had difficulty in producing ocular convergence, and while she was not relaxing her musculature by an effort, rigidity, or muscle tension, supervened. In other words, the higher centres were often invoked to carry out movements which in health were automatic. The Parkinsonian syndrome was usually associated by workers with lesions of the basal ganglia, and the progressive sequelæ of the disease supported this idea. He had seen a number of cases of progressive hemiplegia, starting in one limb and later becoming double. It was mainly a motor disability, but slight sensory disturbances of cortical origin accompanied it. These patients had no arterial degeneration. In one or two, on his advice, an exploratory operation on the brain had been done, but no gross changes were found, and he thought these symptoms might be a hitherto unrecognised legacy of the disease under discussion.

Dr. Buzzard, in conclusion, said that the practical lesson to be derived from the experience of the last few years was that no minor ailment which gave even slight evidence of organic nervous lesions should be treated with anything but the greatest consideration. Inactivity was essential when dealing with inflammation in any part of the body, and the organ which contained the most highly specialised and delicate tissues in the body was no exception to this rule.

Discussion.

Prof. A. J. HALL (Sheffield) dealt with the subject as he had encountered it in Sheffield, and illustrated his remarks by means of a number of slides giving statistics and tracings of temperature and of attacks of polypnœa. In the city in question there were notified this year to October 320 cases, and the surrounding neighbourhood brought the number to about 500. He gave a history of the epidemic in the Sheffield area and stated that the mortality had been surprisingly low, about 10 per cent., in contrast to the 20 per cent. in the country generally. The outbreak was notable for the many variations in type. Six cases in one week were sent into surgical wards as abdominal emergencies; some cases of the disease were diagnosed as pleurisy, others as renal calculus. Hiccough was a very common and distressing accompaniment. The occurrence of abdominal myoclonus led to many mistakes in diagnosis. When polypnœa occurred it constituted a valuable early sign of the disease, and the tracings of respiration during these attacks evidenced the severity of the seizures. He had practically never seen this polypnœa in girls, all the cases were in boys. The attack of this was preceded by a state of anxiety, with deep flushing of the skin of the whole body. A peculiar feature in many of the victims of the disease was a sort of writing mania; a number of the patients spent a great deal of time in scribbling all sorts of things on scraps of paper.

Prof. J. **McINTOSH** referred to the investigation which was undertaken on behalf of the Local Government Board when the disease made its first appearance in England in 1918, and a number of people regarded it as a form of cerebral poliomyelitis, others as an aberrant influenza, but without bringing evidence in support of their contentions. In 1919 a monkey was successfully inoculated with the disease, developing tremor and definite paralysis, and the basal ganglia showed lesions identical with those of human encephalitis lethargica. Many rabbits had since been successfully inoculated with the virus from acute cases, and this animal was much more susceptible to it than the monkey. It was shown that the filtrates from emulsions from infected brains could pass the Berkefeld filter, and the virus could be passed in series from one animal to another. He had himself done four positive inoculations from fatal human cases. He dealt at some length with the criticisms which had recently been brought forward against these experimental findings. He pointed out the difference from spontaneous encephalitis of rabbits, which was always a chronic disease with wasting. The exact relationship of the virus of encephalitis lethargica to that of febrile herpes was much more difficult to evaluate, but he could not bring himself to the view of Levaditi and Harvier, that they were identical. These points could only be settled by a continuance of experimental work.

Dr. A. **SALUSBURY MACNALTY** spoke on the epidemiological side of the question and gave the following table of cases which had been notified in England and Wales from 1919 to the present time:—

Year.	Cases.	Death.
1919	541	264
1920	890	471
1921	1470	724
1922	454	337
1923	1025	530
1924 (to Oct. 25th)	4605	Not yet compiled.

This year's outbreak started in January last and was first localised in Lancashire, originally in outlying districts, then in denser populated districts. There had been a number of instances of several members of a household being attacked, and similar occurrences had been reported in France. From a study of the epidemiology of the disease, the conclusion that encephalitis lethargica was an infective disease liable to manifestation in epidemic form seemed to be justified, and was gaining universal acceptance.

The **PRESIDENT** recalled some cases in his own practice which were diagnosed and treated in various ways and which, on further knowledge, seemed to have been instances of this disease. One in particular was regarded as tuberculous meningitis. One patient still had diplopia and was probably an ambulatory case of encephalitis.

Dr. A. W. M. **ELLIS** spoke of a number of specimens of urine he had examined from cases; in these there was an absence of phosphoric acid, and the ammonia was far in excess of the normal. These urines also contained a great deal of albumose, pointing to considerable liver involvement.

Dr. C. P. **SYMONDS** spoke of cases of encephalitis lethargica who had the Argyll Robertson pupil. With regard to the restlessness and insomnia of these cases, he questioned the wisdom of seeking, by the aid of hypnotics, to reconstruct the normal rhythm. If new symptoms were not manifested, his experience had been that the patient tended to re-establish the normal rhythm naturally.

Sir **WILLIAM WILLCOX** said that nearly every case of the disease he had seen had a rapid pulse, but one definite case, in a boy, had a pulse of only 50. He asked as to the value in diagnosis of the paralysis of accommodation when it occurred; also whether Dr. Buzzard found that the prognosis in the condition was worse for patients over 55 than in younger persons.

Reply.

Dr. **BUZZARD**, in the course of his reply, spoke appreciatively of the work which Prof. Hall had done in connexion with this disease. He was much interested in his remarks about hiccough. In one school where there was a mild epidemic of encephalitis, the school medical officer told him that four of the masters had such violent and continuous hiccough that they were unable to control their forms, and had to be absent from school until the symptom passed off. He agreed with Prof. Hall that many of the cases seen were of a desperate nature, when there was a rapid termination in death of the Parkinsonian syndrome. Still, in the first case in which he, the speaker, saw the Parkinsonian syndrome, in April, 1918, the patient, a man aged 50, was bedridden with what looked like paralysis agitans, but this year he found the man was back at his work on a railway. He had seen cases with both a quick pulse and a slow one, and he was not prepared with an explanation of the difference. He thought those with a slow pulse had reached a considerable degree of lethargy; indeed, some were almost stuporose, as if they had increased intracranial pressure, and probably the pulse partook of the general sluggishness. He agreed that the prognosis in older patients—about 60 to 65—was usually worse than in young adult life. In one household every member and the servants were stricken with the disease, most of them mild cases, and it was regarded as some gastro-intestinal infection, with neuritis. The mistress had the fulminant type and was dead in ten days. The intestinal tract might be one method of approach of the virus to the central nervous system. In answer to Dr. Symonds, he did not think one could make much difference to the rhythm of patients troubled with insomnia and restlessness. The hiccough, he had found, was best relieved by chloretone. With the careful study of the symptoms and histories, and comparisons of results, there would develop a greater confidence in diagnosing this disease than many felt at present; but it was a condition which well merited every form of investigation which could be brought to bear upon it.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting of this Institution on Nov. 6th a discussion took place on the

Treatment of Pleural Empyema.

Mr. **THELWALL THOMAS** alluded to a discussion held in 1893, when he brought upon himself serious criticisms for daring to advocate excision of a portion of rib to facilitate free drainage. He discussed empyema with and without pneumonia, and emphasised the necessity in severe cases of empyema, complicated with pneumonia, of repeated aspiration to relieve serious symptoms of toxæmia and asphyxia before resorting to incision—a mode of treatment confirmed during the severe war epidemic. He strongly advised local anæsthesia both as a preliminary to exploratory puncture and as the only method of anæsthesia for the subsequent operation. The site of election was below the angle of the scapula, a portion of the eighth or ninth rib being excised and the pleural opening being made sufficiently large to admit two fingers and facilitate removal of masses of fibrin. Since the routine performance of this operation chronic empyema had been much less frequent. He mentioned the value of X ray examination in doubtful cases. Tubes for drainage should be half an inch in diameter at least; he deprecated the use of safety-pins as "land anchors" for the tube, suggesting instead a strong hair-pin pushed through the tube and the limbs bent at right angles. Chronic cases necessitating Dakinisation or plastic operations had become rare owing to efficient drainage. Antiseptic dressing should be used. Exercises to extend the lungs and good feeding were essential. The operation of incision, drainage, and immediate closure he considered severe and uncertain as to result.

Mr. **JOHN T. MORRISON** said that out of the large number of interesting questions raised he would confine himself to one, the prevention of the development of chronic empyema. This might be looked at from two points of view, the early expansion of the lung and the prevention of infection. The first should be encouraged from the start. The ideal method, primary closure of the wound, being still too risky for general use, valvular drainage should be employed. Personally, he favoured connecting up a short wide drain with a tube hanging over the bed, its end under the surface of fluid in a bottle on the floor. The tissues must, of course, fit snugly round the drain. This made an air-tight and water-tight joint so that there was no necessity to touch the dressing for five to eight days. The prevention of mixed infection was impossible if the wound remained open. If possible the drainage-tube should be removed at the first dressing; it might be as early as the third day to the fifth if the lung had expanded and adhered to the parietes round the drain as it often did. The early removal of the drainage-tube appeared to him the safe and reasonable compromise between immediate suture and prolonged drainage of the chest.

Sir JAMES BARR said that he had incidentally dealt with the treatment of empyema in his Bradshaw lecture, and in a lecture on the physics of the chest; he should now content himself chiefly with the physics of the problem. When the evacuation of the pus was necessary by an operation, the object should be to prevent, as far as possible, the collapse of the lung. The incision should be made posteriorily as low as thought desirable in a line with the lower angle of the scapula. The patient should lean towards the affected side and an assistant should compress that side of the chest. A short tube should be kept in for a few days to prevent the wound closing, and the wound should be covered with a piece of sterilised oiled-silk, so as to act as a valve to prevent air entering, but allow the pus to escape. The patient should frequently blow into a Woolf's bottle or piece of rubber tubing to keep the lung expanded. When there was a rise of temperature, the surgeon frequently concluded that it was due to lack of free drainage and retention of pus, and proceeded to enlarge his wound and work further mischief, whereas the rise of temperature was practically always due to secondary infection of the wound. When the wound was dry and glazed, constant irrigation should be at once adopted either with Dakin's tubes or by immersion in a warm saline bath. The water in the bath should contain 0·9 per cent. of sodium chloride. The attention to minute details was necessary for success.

Mr. K. W. MONSARRAT considered that the appropriate treatment of empyema was dictated by the type of infection in each case. In streptococcal cases an early thoracotomy was often inadvisable. In tuberculous cases the results of open operation were usually disappointing; sinuses in these cases tended to persist indefinitely. In pneumococcal cases he held that there was no rival to adequate drainage, every possible measure being taken to dispense with tube drainage at the earliest moment. He did not use any special measures; he considered that the essentials of technique were: an opening wide enough for the evacuation of coagulum masses, and a tube large in diameter and short in length. Examination of the discharge was the best guide in choosing the time for dispensing with the tube.

Dr. HUBERT ARMSTRONG recalled the danger of acute œdema of the lung and syncope in exploratory puncture, but denied that it could be averted by previous local anæsthesia. There was no such danger in the exploration of an empyema, but only when the needle entered the lung in chronic pneumonia. He considered it advisable to aspirate in cases where the fluid was only turbid, and to postpone open operation till it had become frankly purulent. The extremely low operation was not without danger of injury to the diaphragm and consequent infection of the peritoneum.

Dr. J. C. MATTHEWS referred to those cases (usually following pneumonia) where aspiration produced a thin, turbid fluid with a high bacterial content. It was well recognised that these cases, if submitted to immediate operation, became very ill; he suggested that this was due, not so much to the infective nature of the fluid, but to the fact that, in the absence of adhesions between the lung and chest wall, operation induced a complete pneumothorax with its consequent collapse of the lung and displacement of the mediastinal contents to the opposite side.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

AN ordinary meeting of this Society was held on Nov. 6th, Dr. E. F. MAYNARD, the President, occupying the chair. Dr. W. BARRINGTON PROWSE read a paper entitled

Deep X Ray Therapy.

He said in the past there had been much uncertainty and want of method in the application of X rays for therapeutic purposes, the result being disappointments and doubts as to the value of the treatment in many directions. It was not claimed that X rays were a complete cure for malignant disease, but they offered a prospect of cure in some cases. The main purpose of his paper was the subject of X rays in relation to malignant diseases, and in particular he wished to speak of the more scientific and accurate applications of X rays for therapeutic purposes, especially as employed at Erlangen. The work of Profs. L. Seitz and H. Wintz at that University had raised deep therapy to the rank of a scientific and accurate procedure, leading to greatly improved results. Even by the older methods relief of pain, healing of ulcerated surfaces, disappearance of a growth, at any rate for a time, had been effected, but measurements and dosage were variable. Now the dose could be measured fairly accurately both on the surface of the body and at given depths, and the reactions of normal and diseased tissues to different quantities of rays, which had been established, gave us some basis for the dosage. Apparatus also had been devised enabling the use of the necessary heavy and accurate dosage of rays of sufficient penetrating power and homogeneity. X rays had a profoundly destructive action on all tissues when administered in sufficient quantity. Smaller doses appeared to stimulate, though this had been disputed. While the action of X rays on all living tissues was similar it varied in degree, according to the tissue. Young and rapidly growing cells, such as those of embryonic type, were more susceptible than older cells of fixed type. The cells of new growth, being largely of this embryonic type, were all (though in varying degree) more susceptible than most of the body cells of fixed type. Seitz and Wintz at Erlangen had measured quantities of X rays which produced biological changes in tissues normal or diseased, while Kronig and Friedrich, of Freiburg, working on a different system had arrived at similar results, giving the same relative sensitiveness of individual tissues. These give a basis for estimating the necessary dosage in deep X ray therapy. Dr. Prowse defined the latter as the administration of an accurately measured quantity of rays, for curative purposes, to the whole of a diseased area within the body, such quantity being the minimum which would cause the destruction of the vitality of the diseased tissue to which it was applied. In the accurate measurement lay the difference between this and the older methods. Depth was variable—the tissue treated might lie in the centre of the body or at the surface—and he did not like the word "intensive," ignoring measurement and conveying the impression of extreme intensity, though this was no greater than in the older methods. The treatment was intensive in the sense that it aimed at giving the full necessary dosage within a short time instead of in divided doses over a long period. There was a division of opinion on the relative merits of the above methods, but he thought the immediate application of the total dose to be the method of choice when dealing with an *existing* malignant growth, except where there were positive contra-indications, though there were, of course, cases in which it was not advisable. Ten years ago it had been noticed that malignant growths exposed to X rays gradually suffered diminution of their sensitiveness to the rays, and Sidney Russ had recently further established by experiments on rat sarcoma that this acquired resistance was handed down through many generations of cells, descended from those originally irradiated. This was a strong argument in favour of the immediate application of the total dose. The single dose was more accurate, smaller in quantity in the end, and effected a saving in time, which was important in dealing with cancer. Those who advocated divided dosage laid stress on the fact that recovery from these doses was more rapid in the normal tissues than in the tumour and on the absence of X ray sickness; they pointed out the great general disturbance of the body frequently seen after the single dose, the changes in the blood, and the possible injury in the healthy organs. These latter dangers might also be present in the divided dose. Dr. Knox had suggested that the *control* of cancer and other diseases by radiations in divided doses should be aimed at, but was this possible? Many cases of cancer had been checked in their progress by X ray treatment carried on at intervals, but in the end had succumbed, and after a time X rays had appeared to lose their power. Dr. Prowse did not suggest that the single lethal dose was applicable to every case. Each case must be considered on its merits, and the arguments against the single massive dose had more weight in cases other than those of *existing* malignant disease. The prime object of the Erlangen treatment of cancer cases was the destruction of the vitality of the cancer cells. There followed breaking down of the cancers, elimination of the products of disintegration, and building up of healthy tissue. Wintz attributed the first of these entirely to the "destructive momentum"—namely, the X rays; elimination depended on the general biological condition of the whole body.

In dealing with a case sent for X ray treatment, the first thing was verification of the diagnosis, but there was objection to test-excision or curetting if avoidable. Then the general condition of the patient must be considered. The size of the tumour was important: first, on account of the possible difficulty of producing a lethal effect upon all parts of it; and secondly, on account of the general reaction which might result from the destruction of a large growth in situ and the question whether the body was equal to the strain of elimination and recuperation. Further inquiries should cover metastases, blood, excretory functions, previous illnesses, skin—especially as regards former irradiations or applications capable of producing irritation or secondary radiation. Possible adhesions fixing coils of intestine within the area of irradiation were very important, also inflammatory states of the intestine or bladder. Close collaboration was necessary between medical attendant, radiologist, and surgeon. Preparation of the patient for irradiation should include rest, effective emptying of the bowels, regulation of diet. Some abdominal and pelvic cases were irradiated fasting. Sometimes an injection of heroin or morphia and scopolamine was necessary.

With regard to general considerations of irradiation, the object was to apply to the whole of the diseased area a dose of X rays suitable for the destruction of the vitality of the malignant cells, without serious injury to the skin and normal tissues. This was generally more easily done in the case of centrally situated tumours than in the case of those on the surface. When the tumour was on the surface it became in some ways more difficult to get sufficient dosage without injury to the skin. The total time required for the irradiation might be several hours, and it was often necessary to take the dose in instalments (bearing in mind that the dose was to be completed within about two days) and all possible provision must be made for the patient's comfort and for the protection of those parts not at the moment within the field of irradiation. After-treatment was as important as irradiation, since after the destruction of the vitality of the malignant growth, reparation of injured healthy tissue, elimination of products of disintegration, the sustaining of the body against malignant disease, and the restoration of healthy tissue had all to be undertaken. These depended mainly on the condition of the body, but rest, fresh air, attention to excretion, and suitable diet were all of assistance. Wherever local irradiation has caused local lowering of vitality, the tissue or organ affected must have rest as far as possible, and must be protected from all sources of irritation.

Among general injuries, X ray sickness might appear in greater or less intensity and was generally lessened by regulation of the bowels before irradiation and administration of a hypnotic. Injury to the blood depended directly upon the quantity of rays absorbed and generally righted itself in about six weeks, but should be helped by medicinal treatment and fresh air and sunlight, &c. For elimination of the products of disintegration and restoration of healthy tissue we had to depend upon the resistance of the body, only removing as far as possible all sources of irritation, and upon general care and treatment. X ray therapy for carcinoma might seem a formidable proceeding, but carcinoma was a formidable disease and seemed to justify risks.

Discussion.

The President said he had read Erlangen reports and was sorry to find the results claimed had not been substantiated.

Dr. Henry T. Cubbon asked if enlarged thyroid had been treated by intensive methods.

Dr. C. Guy Whorlow disliked the term deep X ray therapy, but approved of the definition given by Dr. Prowse. There was difficulty in getting together the physicist, instrument-maker, and radiologist. He considered that small doses of X rays stimulated cells, and one must avoid stimulating new growths. He did not agree with an invariable carcinoma dose. Cells varied in radio-susceptibility and cells varied during the period of their life-cycles, the most susceptible stage being during reproduction. A large number of young subjects could be given single intensive doses, but in old people with toxic symptoms the dose should be spread over one week, giving the body time to deal with toxins thrown into system and avoid sickness. Dr. Whorlow also discussed the action of minute doses spread over a long period and large area with a view to producing immunity to disease. In non-operative cases X rays should be used in all cases for the relief of pain and for improving the general condition of the growth. Radiation in carcinoma mammæ should be given tangentially to prevent any lung complication.

Dr. Thomas S. Allen asked the result of operable cases treated by X rays.

Mr. Fitzmaurice Kelly considered that the procedure should be preliminary radiation of the whole area before operation and small doses after.

Exhibition of Cases.

At the commencement of the meeting Dr. W. B. Prowse showed two cases treated by X rays:—

Case 1: *Sarcoma of the Back.*—The patient was a man aged 60. A prominent sore spot was noticed in January, 1924, by patient. In April a growth the size of an egg was noticed to the left of the spine, also nodules in surrounding skin, growing rapidly and inoperable. Treatment was given on April 28th. Within a week there was appreciable reduction of the tumour and smaller nodules, and at the end of three weeks the growths had practically gone. Second treatment was given on June 21st. Present condition: No sign of growth: supple skin everywhere. General health good and no sign of metastases.

Case 2: *Carcinoma of the Breast.*—The patient was a woman, aged 74, with extensive and inoperable carcinoma of four years' standing. She had a large mass in the outer part of the left breast involving a considerable area of skin and on the point of breaking through in two places. The patient's general condition was good. First treatment on April 14th this year produced some reduction in the mass. Second treatment given June 6th. At end of July nothing was left of the tumour but a puckered scar with a little thickening underneath. A third treatment was given on July 23rd and a fourth on Oct. 3rd. Present condition: A puckered scar, and a little fibrous thickening under it. No sign of metastases and general health good.

The dosage was arranged so as to get, if possible, a lethal effect from a single application. There were no harmful results.

Dr. A. W. **WILLIAMS** also showed two cases: (1) A severe case of lupus vulgaris of nose and upper lip cured by carbon arc-light baths; (2) lupus vulgaris of nose, cheek, lip, buccal mucosa, and larynx, treated by sunlight baths and eosin and sunlight to skin esions.

Dr. H. M. **GALT** showed microscopical slides of: *Sp. pallida* in liver, human lung (doubly injected), normal ovary from a child of 2 months, and the solid part of a dermoid cyst of the ovary.

LUNACY LAW AND ADMINISTRATION.

FURTHER SITTINGS OF THE ROYAL COMMISSION.

(*Continued from p. 913.*)

THE sittings of the Royal Commission on Lunacy and Mental Disorder were resumed on Tuesday, Nov. 4th, under the presidency of Mr. H. P. Macmillan, K.C.

EVIDENCE OF MEDICAL SUPERINTENDENTS OF POOR-LAW INFIRMARIES.

Dr. A. L. Bayly, medical superintendent of Lambeth nfirmary, said the accommodation for mental cases n this institution consisted of four wards with 0 beds for women and one ward with 11 beds for nen; the latter would probably be increased in the ear future. Every degree of mental disability was nanifested by the patients there. A magistrate ttended on two days each week for the purpose of ertification. During the year which ended last March 15 persons were brought before this magistrate, nd of that number 453 were admitted on the request f either the relieving officer or the police (under ection 20 of the Act, which provided for three days' etention). Other cases were transferred to the mental epartment from the general wards of his own or ome other institution. Of the 453 cases on three ays' detention, 193 were subsequently transferred o mental hospitals, in 111 others the orders were llowed to lapse, and the remaining 149 were eventually ither discharged or transferred to the general wards. large number of these cases, he said, were not echnically lunatics, but it was advantageous to the atients that they should be for some time under ontrol. The cases which were transferred to mental ospitals were those amenable to treatment, for which here was no provision in the Poor-law infirmary. ases retained in the infirmary were chronic, most f them senile. His frequent difficulty was, not in eciding whether or not a particular person was of nsound mind, but whether he should be transferred a mental hospital. A good deal depended, in finding n answer to this question, on the kind of home onditions the patient had. Much of this difficulty ould be removed if there were a scheme whereby eople of obvious unsoundness of mind could be laced on trial for a period without certification, pecially as many of the cases of mental unsoundness hich found their way into the Poor-law infirmary ere clearly of temporary nature. In quite an ppreciable number of cases domestic trouble seemed have been the determining factor; in fact, he had ad cases in which husband and wife alternately nt each other to the receiving establishment. he mental unbalancing in these cases usually disppeared shortly after the calming influence of the firmary operated. Cases which observation showed ere not certifiable were mentioned to the magistrate on the latter's visit, and received their immediate discharge unless physical ailment was present, and then, in that case, the patient was sent to a general ward. In certain cases it was not clear that discharge should be granted, and it seemed desirable that further observation should be carried out. These the speaker certified but suspended the operation of the certificate. If during that period recovery took place no one was aware that certification had been effected.

In reply to questions as to his position should an aggrieved patient take action on an allegation that he had been certified, Dr. Bayly said he had received assurances of protection from a Commissioner of the Board of Control, but fear of legal troubles in connexion with this work was now very acute among private medical practitioners, and it caused them to evince a disinclination to participate in the administration of lunacy. Every effort was made by the relieving officer, and, if necessary, by the police, to trace relatives of patients, not only to settle the question of chargeability, but to assist in compiling a reliable history of the patient and to give their wishes in regard to him. Only a small percentage of patients suffering mental accompaniments of fevers were eventually certified, and where insanity was clearly a part of physical disease he always did his utmost to retain the patient in his own institution in preference to sending him to a mental institution. He objected to a hard-and-fast segregation of mental cases. There were advantages in treating mental cases in a general institution, not only because it avoided the "stigma" of insanity, but because it meant the patients then had the advantage of supervision and treatment by a general medical staff. It would suffice if attached to the ordinary staff there were a special mental consultant.

The Chairman emphasised the fact that mental disease disturbed the responsibility of the citizen, and said that while the stay of a patient in a general hospital was necessarily short, mental disease ran a long course, and in many cases was permanent. There was the further point that it was undesirable for mental patients to associate with rational persons.

To this Dr. Bayly said a large number of mental cases were amenable to treatment in a general ward, while for others he agreed a separate ward was needed. For incurable cases it was better to have either a separate block or an entirely distinct institution. If power were to be given to Poor-law institutions to retain apparently curable patients for a longer period than they could at present be kept, it would be necessary that the staff should include experts in the treatment of mental disorder.

The next witness was Dr. J. Dudgeon Giles, who is medical superintendent of Salford Union Infirmary. He said that of 900 patients in his infirmary there were, on the average, about 150 mental cases, and about 80 per cent. of the latter were brought by either the relieving officer or the police, and were kept there on a three days' detention order. A very small number were discharged within that period, and the majority of the total were placed on a 14-day order for purposes of observation. At the end of the 14 days a certain number were found to be certifiable, and accordingly were transferred to a mental hospital. Chronic cases were placed under a permanent detention order. He expressed his strong view that there should be a period of observation and provisional treatment, with some sort of control, before certification was resorted to; but with that should go the power of saying to the relatives that during such period the patient must not be removed from the institution. Such a provision in regard to observation would, he considered, result in more volunteering for treatment and at an earlier stage of their mental malady than was the experience now. He agreed that the present system, as intelligently and sympathetically interpreted by medical officers, had not worked badly, but he thought some simplification was eminently desirable.

EVIDENCE OF OTHER POOR-LAW OFFICERS.

The Commission resumed its sittings on Wednesday, Nov. 5th, when the first witnesses were Mr. Howard Senior, President of the National Association of Masters and Matrons of Poor-law Institutions, and Mr. Usher, its hon. secretary, whose evidence reflected the expressed opinions of 1000 institution officers. They both stated that they considered there should be a longer period of observation in regard to persons regarded as of unsound mind who had been admitted to workhouses, where at present the period of detention was 14 days. Quite 50 per cent. of the people who came in under temporary orders were cured, so that certification became unnecessary in that number. In small institutions the officer of the infirmary had to do the best he could under the circumstances, and if the police brought in an acute case—without an order—the absence of properly trained people rendered the position a very difficult one. They did not consider that any country house was suitable for the reception of cases under Sections 20 and 21; their suggestion was that one institution in each area should be set apart for the reception of cases of the kind and staffed accordingly. Chronic cases, such as those of senile dementia, were living with the rest of the workhouse inmates in a number of country places, and apparently without detriment. Sometimes such patients, who had shown no harmful tendencies, were allowed out for short periods, the master of the workhouse taking the risk. Asked if their views would be met by having a special department of the mental hospital where patients could be observed and afterwards duly relegated they replied in the negative, mainly because of the stigma still held to follow such association. In reply to a question by Lord Eustace Percy, Mr. Usher said he did not see why arrangements should not be made with the Poor-law authorities to set apart one of their institutions in each district for the reception of the kind of cases under discussion. His Association advocated the lengthening of the period of preliminary detention, and eight days should be allowed for arriving at a determination of the nature of a case, and so that these days should not be wasted from the point of view of treatment, there should be at these places facilities for treatment as well as observation.

Mr. Senior said his Association considered that the three-day order should be followed by a magistrate's 14-day order, and that in every case the magistrate should visit the institution and see the patient. He personally believed the period should be made 28 days, and at the end of that time an order for discharge or for detention in an institution should follow. It was very seldom, in his experience, that a justice suspended the execution of an order for not longer than 14 days, as allowed. Answering Sir Humphry Rolleston, he said the patient should be dischargeable at any period within the suggested 28 days, but he would not object to two 14-day periods instead of one of 28 days. If recovery occurred during the currency period, presentation of the medical certificate to that effect to the justice who made the order should suffice to secure discharge. He further contended that the periodical revision of cases should be undertaken by a rota of justices of the peace; the point was to ensure the periodical bringing of cases before some authority. In large institutions the medical officer's quarterly report would be a sufficient protection to the patient; his remark applied to small institutions which guardians did not systematically visit.

Mr. Senior also raised the question of children of very poor mental condition being kept in the same wards as adult chronic mental cases, remarking that the influence was a bad one, as these children proved very apt imitators. Attempts to get such children to other institutions generally failed. He emphasised the importance of the relatives of the adult patient being warned of the case being about to be dealt with by the justices, and inviting a relative to be present to assist in the matter. In the case of mental disorder accompanying physical disease, such as pneumonia or severe neurasthenia, the patient should be placed under a limited order and certification avoided, as disclosure of the latter might militate against subsequent success in life.

EVIDENCE OF JUSTICES.

Mr. L. Whitemore, J.P., a judicial authority in the County of London, next gave evidence, based upon a large experience in dealing with petitions for reception orders in London in the case of private patients. He criticised the present duplication of authorities, which he regarded as unnecessary. He was in favour of the provision of a period of observation before a final judgment was pronounced upon a case. Also some care should be exercised in seeing that when a patient was discharged the destination to which it was intended to send him should be suitable; and he would like the after-care aspect of the question to be more stressed.

The last witness was Colonel P. Broome Giles, F.R.C.S., J.P., who gave his experiences as a justice under the Lunacy Act in Herefordshire, Bucks, and the borough of Folkestone. He said he would make it a sine qua non that the magistrate should personally visit the patient at the latter's home; it had been his own invariable practice. He also asked whether a friend of the patient, other than the petitioner, was present at the interview, and did all he could to bring this about. Cases of alcoholism, puerperal mania, and some of neurasthenia should have a lengthened period of observation before certification was entertained. During this time the patient could be kept in a large house with a resident medical man and nurses to keep watch on him or her. In his experience patients were given every chance of making complaints, and these were always listened to and investigated. In one or two cases ill-treatment had been established, and the attendants at fault were discharged. He had known only two cases in which the magistrate's opinion on a case was against that of the medical man, and in those cases he did not think the magistrate was the right type of man for the position. In his interviews with patients before certification it had not occurred to him to reveal to them his function in case they should wish to put forward a special plea to preserve their liberty; that was because he wanted them to feel no restraint. He had never known a patient discharged without the authority of the medical officer. Facts stated on the certificate to have been communicated by others he had always been careful to personally verify, sometimes asking people concerned whether particular statements were theirs. He would not make such checking by the magistrate obligatory; discretion should be allowed. In the case of complaints by patients while under detention, he talked to them in a locked room alone; he did not fear a homicidal outbreak, as he was once an amateur middle-weight boxer.

The Commission adjourned to a date to be determined.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED NOV. 1ST, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely: Small-pox, 48; scarlet fever, 2238; diphtheria, 1170; enteric fever, 93; pneumonia, 863; puerperal fever, 39; cerebro-spinal fever, 3; acute poliomyelitis, 28; acute polio-encephalitis, 1; encephalitis lethargica, 40; continued fever, 2; dysentery, 4; ophthalmia neonatorum, 102. There were no cases of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 4 deaths from enteric fever, none from small-pox, 7 from scarlet fever, 33 from diphtheria, 29 from measles (a sharp rise), 46 from influenza. In London itself the deaths from diphtheria numbered 9 and from infantile diarrhœa 28.

Reviews and Notices of Books.

THE MAYO CLINIC.

Collected Papers of the Mayo Clinic and the Mayo Foundation. Vol. XV. 1923 (published June, 1924). Edited by Mrs. MELLUISH. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 1377. £3 3*s.*

"THIS volume marks a radical departure from the policy previously pursued in the selection of material for reproduction in the Collected Papers of the Mayo Clinic." Put briefly, whereas in the past an effort was made to reprint all publications—an effort which has been unsuccessful since 1917—now, though every paper is at least mentioned, not all are set out in full. The volume is kept within reasonable limits by giving either brief abstracts or by merely citing the reference to the original publication. The articles chosen for this treatment are those of technical or limited interest to the few rather than of general interest to the surgeon or physician.

The arrangement of the volume is similar to that of its predecessors. Subjects are dealt with by systems beginning with the alimentary tract. As usual, this section is of especial interest and contains much that is of great value. The articles from Russell Carman on the technique of gastric and intestinal rontgenology, and the findings in diseases of the whole alimentary tract represent the latest advances in this difficult subject. In this respect the publishers must share in our congratulations on the high technical achievement in the reproductions of X ray films. The urogenital section contains some excellent articles, of which the most instructive concerns diverticula of the bladder from the pens of Starr Judd and Albert J. Scholl. They hold the view that these sacs are of developmental origin, but only become the cause of symptoms later in life, the age of the prostatic enlargement accounting for nearly 70 per cent. of the total. Of 133 cases seen at the Clinic between 1894 and 1923 only two occurred in women. They favour removal by the extravesical route in most cases, and report an 8·1 per cent. mortality. In only five cases was the ureter involved, and in 20 there were associated calculi. Of these, in nine cases the calculi were in the diverticulum, eight in the bladder, and three in both the bladder and the diverticulum. In their series ten of the cases showed a carcinomatous change. The sections on ductless glands, circulatory organs, skin, head, trunk and extremities, and the nervous system all contain numerous papers of importance, pointing to the extensive work being carried out at the Clinic. One article perhaps may be singled out as being of surpassing interest. It deals with the problem of the administration of insulin by overworked general practitioners, and it contains helpful advice on this difficult subject. The section of technique contains three articles all dealing with local and regional anæsthesias in various regions. The first is by Starr Judd and William Meeker on sacral block anæsthesia in the surgery of the prostate and the bladder, and outlines the method of blocking the sacral nerves at their exit from the sacrum. The second—by William Meeker and Herman Hundling—describes and comments on the various approaches to the cervical plexus. For several reasons they advise the lateral oblique route, by which the needle is inserted just below the mastoid process on the mastoid-cervical tubercle line and directed obliquely downwards, injections being made where the nerves lie in relation to the cervical vertebræ. They conclude that the neck is one of the most favourable regions for local anæsthesia, and they advise use of this method in thyroidectomy, thyrotomy for removal of tumours, laryngectomy, œsophageal diverticula, for removal of glands, branchial cysts, tracheotomy, and ligation of blood-vessels. The third article by W. Meeker and Barnet Bonar describes the use of regional anæsthesia for gynæcological and obstetric operations.

The volume is prepared with the same care and thoroughness which has always characterised Mrs. Melluish's work, and the general get-up and the illustrations are of high standard. The appearance of these volumes from the Mayo Clinics is one of the landmarks of periodical medical literature, and we believe them to afford busy medical men one of the surest means of keeping abreast of the times.

THE NATURE OF DISEASE.

By J. E. R. MCDONAGH, F.R.C.S. London: William Heinemann. 1924. Part I., pp. 327. With 59 plates. £3 3*s.*

IT is often supposed that imagination has no place in the progress of natural knowledge. People sometimes think that Darwin learned all the facts of biology and then found that they inevitably added up to the theories which he put forward in the Origin of Species. In fact, of course, the theory came into his head first of all, and he then spent a good many years reading the literature and making experiments in search of facts to illustrate and demonstrate it. The question of the proper share of the imagination in scientific work has often been discussed with no more profitable result than the conclusion that some people have the faculty of using their imagination in such a way that the highest type of progress ensues, and that others are led by their imagination into what is just nonsense. The history of science has plenty of examples where subsequent knowledge has entirely disproved a contemporary judgment that an author belonged to the second class. In view of which it is obviously wise to suspend one's opinion and leave the point open for each reader to decide for himself. But Mr. McDonagh's book is a large one, remarkably tedious to read, and in parts impossible to understand; and it is hardly fair to encourage others to embark on it without passing the opinion that they will probably come to the conclusion that Mr. McDonagh uses his imagination in an illegitimate way.

In more detail, the book is mostly about syphilis, and a good deal of it seems to have been published before. The author deals with the life-cycle of the spirochæte, the theory of staining, the inflammatory response in epithelium, endothelium, and leucocytes, chemotherapy, blood coagulation, the Wassermann test and shock, and the whole centres round his conception of condensers and conductors and their action on the protein particles of the blood. Further parts are promised as the author's investigations proceed.

OPERATIVE SURGERY.

By W. S. BICKHAM, M.D., F.A.C.S., former Surgeon in Charge of General Surgery, Manhattan Hospital, New York: former Instructor in Operative Surgery, College of Physicians and Surgeons (Columbia University). London and Philadelphia: W. B. Saunders Company. In six volumes. Vol. IV. 1924. Pp. 842. £15 the set.

THE fourth volume of this work carries out the general plan and intentions of the author as evinced in the preceding parts already reviewed in our columns. It deals with operations upon the heart, pericardium, and thoracic œsophagus, abdominal surgery in general, except the colo-recto-anal regions, and abdominal gynæcology. There is the same encyclopædic description of operative procedures which have been devised and used. The surgeon in consulting the book will always have to select his methods for himself in the light of his own knowledge or the experience of others, but he will very seldom fail to find a clear account of any operation he may wish to perform. Curiously enough, no account is given of the inguinal method of operating upon femoral hernia, nor, for that matter, of Roux's method In diaphragmatic hernia the combined abdomin and thoracic approach has been highly spoken by some surgeons. A description of it would ha been helpful. Such ill-advised procedures as gast pexy and gastroplication are described as though they were commonly carried out, whilst the same remark may be made of the use of Murphy's button for gastro-jejunostomy and other anastomoses. The section on surgery of the biliary tract is particularly good. Where such an enormous field is covered it is easy to find examples of omissions here and there. They are, however, commendably few, and the author is to be congratulated on maintaining the high standard set by the previous volumes.

DEAF-MUTES.

Les Sourds-Muets. Étude médicale, pédagogique et sociale. By DR. G. DE PARREL, former Chef de Clinique, and Mme. GEORGES LAMARQUE, Professor, at the National Deaf and Dumb Institution of Paris. Paris: Les Presses Universitaires de France. 1925. Pp. 445. Fr.35.

THIS excellent work deals in a very complete manner with the whole problem of the deaf and dumb child. The first part has the more direct medical interest, and begins with the classification of deaf-mutism; the main division into hereditary and acquired, not into congenital and acquired, is insisted on. Ætiology is fully discussed, and the preponderant rôle of syphilis is emphasised, while a distinction is drawn between congenital syphilis and the "syphilitic heredity." A very full description is given of the complete medical examination of the deaf and dumb child, in which a careful examination of the eyes, and correction of visual defects, are rightly insisted on. There is an interesting chapter on the care of the child before school age, which should be of great value both to the parents and doctor; exercises at home, preparatory to formal instruction in lip-reading, are included in this chapter, and form an important part of the treatment too often neglected. The second part of the book deals with the educational aspects of the subject; the deaf and dumb schools of France are fully described, together with the details of the methods of instruction which are employed; and, finally, the civil and social position of the deaf-mute, and his prospects and attainments are discussed.

The book is written with knowledge, sympathy, and enthusiasm, and deserves to be read by the many who are, or should be, interested in the subject.

SURGICAL DISEASES OF THE DOG AND CAT.

With Chapters on Anæsthetics and Obstetrics. Third edition. By FREDERICK T. G. HOBDAY, C.M.G., F.R.C.V.S., F.R.S.E. London: Baillière, Tindall and Cox. 1924. Pp. xii.+435. 15*s.*

THE third edition of this book has been eagerly looked for, for the second edition has been out of print for some years. The application of aseptic and antiseptic principles to the surgery of the dog and cat has enabled great advances to be made in the art of treating injuries or diseases by operation. The internal diseases of the abdominal and pelvic cavities of the dog and cat were more or less closed ground as regards diagnosis and treatment until laparotomy was initiated. Major Hobday was one of the first in this country to carry out laparotomy on a large scale on these animals, and his book is therefore of especial interest to veterinary surgeons.

The successful anæsthesia of a canine or feline patient is as important as the proper carrying out of the operation. The instructions and advice here given on local and general anæsthetics may be accepted as authoritative since they are based on thousands of records extending over a period of some 30 years. The various regions of the body and the diseases or mishaps that may necessitate surgical procedures are dealt with in order, the eye, ear, mouth, throat, neck, stomach and intestines, rectum and anus being discussed in separate chapters.

The account of operations on the urinary organs and male and female generative organs is specially lucid and a valuable chapter is added on Difficult Parturition. The application of X rays to the diagnosis of canine and feline ailments is well discussed. Illustrations from actual photographs of diseased and pathological conditions are included and greatly enhance the value of the book, which may be read with advantage by all who are interested in comparative surgery.

COMPARATIVE ANATOMY.

Vorlesungen über Vergleichende Anatomie—Ernährungsorgane. By OTTO BÜTSCHLI, Professor of Zoology in Heidelberg. Berlin: Julius Springer. 1924. Pp. 380. $6.45.

THIS book consists of an account of the digestive organs of all classes of animals. Two-thirds of the volume are devoted to the invertebrata, the remaining third to the vertebrata. The author has succeeded in compressing an immense amount of information into the comparatively small space of 380 pages. The book contains many illustrations, mostly line drawings, which adequately fulfil their purpose. Fig. 188, which shows the palate and cheek papillæ of the deer, is a new and welcome departure from the usual text-book illustration. As this work appeals to the teacher and research-worker rather than to the student, it is greatly to be regretted that there is no bibliography.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXVII., No. 4. Pp. 349–469. October, 1924.—Histological Observations in an Unsuspected Case of Epidemic Encephalitis in a young child, by C. Da Fano and Helen Ingleby (London). A child developed symptoms like those of juvenile amaurotic idiocy after an attack of whooping-cough and slowly grew worse, dying of broncho-pneumonia a year after the onset, at the age of 2½. The brain showed the lesions of chronic epidemic encephalitis with widespread degeneration of nerve cells and intense proliferation of endothelium and neuroglia. "Minute bodies" were present. The lesions are fully illustrated.—Pathological Changes in the Musculature of the Alveolar Passages in the Lungs, by J. Harkavay (Freiburg). An interesting study of changes in the musculature of the finer ramifications of the air-passages. Hypertrophy occurs whenever there is chronic obstruction to expiration (e.g., chronic cardiac disease, emphysema), but not in inflammatory lesions, and indicates an active rather than a passive rôle for these fine strands of muscle, particularly in association with the blood-vessels, to which inadequate attention has been paid hitherto.—Urea Retention in Experimental Oxalate Nephritis, by J. S. Dunn, the late A. Haworth, and Nora A. Jones (Manchester). A series of urinary and blood analyses in experimental nephritis in rabbits which are particularly interesting in comparison with the present vogue of similar measurements in man. Oxalate nephritis seriously impedes the excretion of urea, which accumulates in the blood, but not that of water.—The Complement-Fixation Test in Tuberculosis, by F. Eleanor Williams and Lucy M. Bryce (Melbourne). As others have found, the test is useful but not infallible.—The Modification of the Bone Lesions in Rickets due to Mobility of the Part, by J. P. McGowan (Aberdeen). Imperfect calcification leads to mechanical weakening at the epiphyseal junction, and the mobility and even dislocations resulting from this are the cause of many of the gross anatomical changes and the fibrosis of the marrow which occur in rickets and scurvy.—Rats and Foot-and-Mouth Disease, by J. M. Beattie and D. Peden (Liverpool) (see p. 1028).—Bone Marrow Embolism of the Lungs in a Rabbit, by J. S. Dunn (Manchester). Figures and describes pieces of bone marrow found in the lungs of a rabbit after fracture of vertebræ.—The Bacteriology of Fowl Typhoid and Allied Infections, by J. W. Edington (Sheffield).

ery careful cultural agglutination and complement-leviation tests show that the two organisms, *B. allinarum* and *B. pullorum*, which cause fowl typhoid nd bacillary white diarrhœa, are indistinguishable; oth are quite different from *B. avisepticus*, which auses fowl cholera. Three local epidemics were due o *B. pullcrum*.—Fermentative Reactions of the iphtheria Bacillus, by C. C. Okell and E. M. Baxter. he fermentative reactions of real diphtheria bacilli re uniform and constant.—The Experimental Study f Gastrotoxic Serum, by C. Bolton (London). olemical.—Differentiation of Streptococci on Chocoate Blood-agar, by H. W. Crowe (Harrogate). etails of the reactions of a number of strains on the uthor's medium are given, with some correlation of he scheme so obtained with other classifications.—natomical and Parasitological Details of Two Cases f Streptothrix Infection, by H. A. Haig (Cardiff). ne due to *Nocardia israeli*, the other, in which the eart was involved, to *Nocardia bovis*.—Diphtheria of owls, by W. M. Crofton (Dublin). On the evidence f cultures and the success of prophylactic immunisaion the author thinks that fowl diphtheria is due o an influenzoid bacillus.—Obituary notices of . Emrys-Roberts, A. C. O'Sullivan, G. A. Wyon, . Beaton, B. H. Wedd, and A. Haworth, with ortraits of E. Emrys-Roberts, A. C. O'Sullivan, and . G. Shattock, and an index are included.

BRITISH JOURNAL OF SURGERY.—The October umber contains Sir D'Arcy Power's fourteenth Eponym—the Wheelhouse Operation.—W. A. Cochrane escribes a method of treating fractures of the leg nd ankle by plaster of Paris, and the overcoming f residual deformities by wooden wedges introduced nto cuts in the plaster cast.—G. Keynes records hree cases of squamous-celled carcinoma of the enal pelvis.—R. J. M. Love brings forward some emarks on prognosis in acute appendicitis.—S. Pringle describes a new method for the aseptic esection of the intestine.—R. F. Young records ive cases of polycystic kidney and briefly reviews the ausation, symptoms, and treatment of this condition. —T. H. Burlend and D. J. Harries publish their case f a white myeloma at the lower end of a radius n a girl of 9 years. Their resection of the bone was ollowed by a beef bone graft, which was shown adiographically to be slowly absorbed. They find hemselves in agreement with the recent Edinburgh teaching that myelomata are tumours of osteoclasts nd not marrow tumours.—H. A. Bruce reports plexiform neuro-fibroma of the solar plexus.—Prof. C. A. Pannett records his methods and his results in a series of cases of duodenectomy for uodenal ulcer.—Sir G. Lenthal Cheatle adds a ninth case of Paget's disease of the nipple to his previously published series in this journal, Volume XI. —A long and most interesting paper on the transplantation of the fibrous tissues in repair of anatomical defects, by W. E. Gallie and A. B. Lemesurier. They show how fibrous transplants may be utilised in injuries to tendons and ligaments, certain fractures, e.g., the patella, certain deformities, and hernia.—Submaxillary salivary calculi are discussed by Hamilton Bailey.—F. Gordon Bell reports three cases of metastatic tumours in bone from the thyroid gland.—A. Maclennan suggests a new method of arthrodesis in the tarsal joints.—H. C. Edwards reviews the chief features of calculous formation in cystinuria.—Retro-peritoneal catheterisation of the ureters is described by Andrew Fullerton for those cases in which changes in the bladder render the usual manœuvre impossible.—M. J. Stewart and T. B. Mouat contributed a valuable article on fibroma of the abdominal wall.—J. Gaymer Jones discusses chronic intussusception and reports 15 cases.—The following rare cases are reported: (1) M. W. Bulman, Volvulus of the Cæcum; (2) A. H. Southam, Sarcoma of the Metatarsus of an Infant; (3) E. W. Johnson, Epithelioma of the Penis; and (4) C. P. G. Wakeley, Fibro-sarcoma of the Orbit with Multiple Secondary Deposits.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

XXIII.—THE MEDICAL LOCUM TENENS.

BY JAMES NEAL, M.R.C.S. ENG.,
GENERAL SECRETARY OF THE MEDICAL DEFENCE UNION.

ANY medical practitioner who acts temporarily as a substitute for another medical practitioner is technically a locum tenens.

A Difficult Position to Fill.

The position of a locum tenens is often very difficult. The practice into which he suddenly enters may be conducted on lines with which he is entirely unfamiliar. The principal may have had but little opportunity of making the locum acquainted with his methods, or of explaining in detail the various cases for which the locum must now assume responsibility. Not only are the patients complete strangers, but the district and local features may be entirely unknown, and as a rule the locum has not even the advantage of knowing the principal. It is not surprising in such circumstances that complaints are sometimes heard of the unsatisfactory character of a locum tenens. Difficulties must necessarily occur when an unsuitable locum is placed in charge of a practice, and the principal should therefore take great care in the selection of a substitute.

It may happen that a medical man in practice is asked to see a patient during the absence of a colleague through illness or other cause. In such circumstances the locum tenens must carefully avoid doing or saying anything calculated to prejudice his colleague's interests, and must on no account consent to remain in attendance on the patient when his colleague is once more available. He may reasonably claim to be remunerated for his services, but that should be arranged with his colleague and not with the patient. Frequently no claim is made for payment, more particularly when the service can be reciprocated.

Mutual Coöperative Schemes.

In many areas it is now quite usual for the local practitioners to arrange systematically to deputise for each other whilst on holiday, and so avoid the necessity of importing complete strangers as substitutes for the absentees. The arrangement works well in many cases, and is highly creditable to those concerned. A very elaborate scheme has been arranged at Leicester in connexion with the Public Medical Service. The benefits of the scheme are limited to those who are prepared to do some of the work of absent members. Each practitioner who avails himself of the scheme is required to contribute £1 1s. a week for the first and second week of his absence, £6 6s. for the third and fourth week, and £8 8s. for the fifth and any further week. The general expenses of the scheme are a first charge on the fund so created, and the balance is distributed in proportion to the number of units to the credit of each practitioner sharing in the work. A somewhat similar scheme has been arranged by the London Panel Committee.

In those districts where successful holiday schemes are in operation the local practitioners are necessarily on good terms with each other, and the practices are carried on with due regard to the best ethical traditions of the profession. It is satisfactory to know that such arrangements are becoming more general every year. In many cases, however, it is not possible for local practitioners to undertake all necessary deputising for each other, more especially at busy times, and for various reasons a whole-time locum tenens must sometimes be obtained from elsewhere.

Agencies and Fees.

Every medical agent has a list of medical practitioners willing to undertake locum tenency work, and can usually supply one suitable for the particular kind of work to be done. Great care must always be taken to verify the registration of anyone employed as a locum tenens, even when recommended by a medical agency. During the last few years many instances have occurred of unqualified persons obtaining such posts, and in one particularly flagrant case investigated by the Medical Defence Union the same individual had been sent to no less than three practices by an agency before it was discovered that he possessed no qualifications whatever. The best medical agencies make it their business to inquire carefully into the suitability of those they recommend, and unless a principal is so fortunate as to have personal knowledge of a practitioner who is available to take charge during his absence, he will be well advised to rely upon the experience of a good agent rather than to employ a complete stranger on the strength of his own assurances. Moreover, when a locum tenens has been employed who is satisfactory, it is very advisable that the principal should endeavour to obtain his services each year.

The fees now paid to a locum tenens vary usually from seven to ten guineas a week, the employer providing full board and lodging and all travelling expenses. It would obviate many difficulties if the principal would explain his domestic arrangements beforehand, the amount of alcohol he allows, the limits he imposes on the use of his motor-car, and other small points, which, if undefined, may be a cause of friction. The engagement commences from the time the locum leaves his home or the agent's office, and includes the time occupied by his return journey. Temporary engagements are usually on a weekly basis, sometimes by the day only, and it is rarely that monthly contracts are made.

Restrictive Covenant.

Although owing to the temporary character of the engagement formal written contracts are frequently dispensed with, it is desirable to have a properly drafted agreement in every case, and the agreement should include a restrictive covenant against practising within a stated distance for a reasonable period of time. This proves of special value if the principal should die and the sale of the practice become necessary. But in all cases where this precaution is omitted there is a danger of trouble arising. Complaints are frequently made that a practitioner has established himself in a district where he has previously been employed as a locum tenens. I am not prepared to say that a man who has acted as a locum tenens in a particular place, possibly for only a week, is for ever debarred from setting up in practice in that locality. But it must be admitted that a man who sets up in practice in a neighbourhood where he had formerly been employed as a locum tenens for any length of time, even if he invariably refused to attend any of the patients of his former employer, would expose himself to suspicions which would necessarily injure his professional reputation.

The principal is entitled to receive all fees earned by the locum, including fees for attending court, or inquests, or for performing post-mortem examinations, though if any of such work has to be done after the engagement has terminated the locum is entitled to retain the fees or to be suitably recompensed for the work.

Questions of Obligation.

When a locum tenens is obtained from a medical agent a fee is usually charged to the principal, payable as soon as the appointment is made. A similar fee is also charged if the principal at any time re-engages the locum, unless it should be done through another agent. If a locum tenens subsequently buys the practice, or a share in the practice, the principal may become liable for commission to the agent on the purchase money, though in some cases the agent stipulates that the commission will only be payable if the purchase of the practice or a share is made within 18 months of the introduction as locum tenens. The medical agent also charges the locum tenens a commission on the salary received, and if the locum tenens should be re-engaged as locum tenens or assistant, except through another agent, a similar commission is payable. If the locum tenens be admitted into partnership without payment of a premium, such commission, if any, as is payable to the agent who originally introduced the locum tenens is usually based on the gross value of the share taken over by the locum tenens.

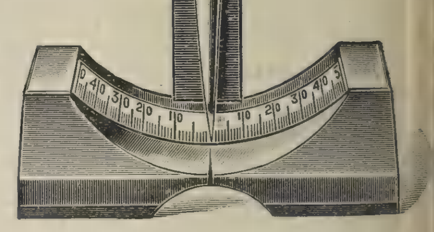
It is important for the principal to remember that the cost of employing a locum tenens—namely, the fees paid to the locum tenens and the cost of housing and feeding him—should be charged as expenses of the practice when making the returns for income-tax.

In law the principal is responsible for the consequences of any act of his locum tenens performed in the course of his employment and duty, this being the ordinary responsibility of the principal for the acts of his agent. But the locum tenens also is responsible in law for his own acts, and the aggrieved party has the right to select whether he will bring the action against the principal or against the locum tenens, or against both. It is most desirable, therefore, that the locum tenens should be a member of one of the medical defence societies, and this might reasonably be made a condition of his employment.

New Inventions.

AN APPARATUS FOR ESTIMATING THE DEGREE OF ROTATION IN THE SPINAL COLUMN.

UP to the present, although many forms of apparatus have been made for the purpose of estimating the degree of lateral curvature in the dorsal and lumbar regions of the spine, no satisfactory one has been produced for measuring the amount of malrotation. To meet this want I have designed a simple apparatus as depicted in the illustration, named the "Spinal Torsionometer." It measures about 4 in. by 2¾ in., and can therefore easily be carried in the pocket. It consists of an aluminium block with a scale to record degrees, above which is suspended a fine needle which immediately registers the angle at which the block is lying. The subject to be examined is placed face downwards on a couch; a line is drawn with a dermograph through the tips of the spinous processes in the region desired together with transverse lines to denote the middle of each such process. The torsionometer is placed transversely on the points of intersection of the line on successive vertebræ and the amount of rotation (if any) is read off. If, instead, the torsionometer be placed longitudinally over each point of intersection, the amount of antero-posterior curve can also be estimated.



The apparatus can be obtained from Messrs. Arnold and Sons (John Bell and Croyden), Ltd., 50–52, Wigmore-street, London, W. 1.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 15, 1924.

PATHOLOGICAL UNITS.

IT was said by one of the greatest of all clinicians hat "To know the natural causes of disease is to know more than half medicine." Pathology is the study of the natural causes of disease and upon its efficient maintenance depends the status of the medical art. Recent donations from the Rockefeller Foundation for pathological departments, and the handsome offer just made known of a gift to the Westminster Hospital of a pathological unit as a memorial to the late Dr. JOHN BURFORD CARLILL, suggest an inquiry into the present position of pathology and the lines upon which it is to develop. Pathology in this country is approaching a critical period in its career as an associate of medicine. In the history of each of the subjects ancillary to medicine and surgery—the two dominant arts in the medical curriculum—there has been the same trend of events, as the subject has grown from being an interesting divagation from the main lines of professional life, pursued by a select few, until it has reached the status and importance of being handed over for its study, teaching, and further development to a specialist. Anatomy was the first to evolve along these lines, physiology followed within living memory, pathology and bacteriology are now separating from the parent subjects. When a pendulum swings it swings back. Extreme positions are taken up before ultimate and ried stability is reached. To many of us the anatomy of our student days was a dry business of systematic ectures upon bones and joints, with little humanising nfluence beyond the contact with comrades in the dissecting room. To-day the dull facts are illumined by the broader conceptions of comparative study and embryological knowledge; the anatomy of the living body is being widely taught by the aid of radiography and the lessons to be derived from the changes induced by disease. Physiology, too, has had its renascence. The frog has been relegated to its proper sphere in he vertebrate world; human and mammalian physioogy are stealing back.

The position of pathology is less definite. It appears o be that of one standing at parting ways, uncertain which to take. Only recently did the pathologist become a specialist; little more than ten years ago W. S. GREENFIELD, whilst occupying a chair of pathology, was holding classes in clinical medicine in he Edinburgh Royal Infirmary. The generation which ollowed, dominated largely by the influence of this doyen of British pathology, developed mainly as eachers of morbid anatomy and morbid histology, nd of them it may be said that they have raised hese branches of pathology to a singular level of xcellence. This exclusive specialisation has, howver, brought in its train certain penalties. A gradual process of drift has led to a separation rom clinical interests, and too close an attachment to morbid anatomy has caused a loss of dequate consideration for the pressing problems of he clinician. The latter cannot evade his share of esponsibility, for too often he has come to regard the pathologist as a useful though modest addendum to he hospital staff, able to give enlightenment upon he cause of death which he has failed to discover but whose possible usefulness at an earlier stage of the patient's downward course had not entered his mind. The clinician and the "pure pathologist," obsessed by morbid anatomy, must between them accept the paternity of that ungainly hybrid the "clinical pathologist," who is often condemned, during the hours of his hospital service, to carry out uninspiring diagnostic tests that could be done quite well by a technical assistant under supervision, and to make up vaccines in his spare time. The artificial separation of two intimately connected branches of medicine has deprived each of the parties concerned of the natural benefits which should arise from coöperation and has diminished their individual professional usefulness. The pathologist on the one hand is tending to submerge the earlier clinical instincts which led him into the study of medicine, and to turn his natural bent for investigation from the clamant but elusive problems of disease towards the solution by animal experiments of problems of his own conception; while the clinician on the other has to rely upon diagnostic tests performed by someone in a distant laboratory. Where this lack of conjunction is most complete it leads to the production of a quite unwanted race of physicians, skilled enough in the arts of AUENBRUGGER and LAENNEC, but inadequately versed in modern scientific methods and wholly lacking in that mental outlook which daily familiarity with research and its sorrows engenders.

Pathology, as we have said, is at a parting of the ways, and just as many young men hesitate in the choice between a life in clinical medicine and a life in the pursuit of natural knowledge, and often fall into ineffective attempts to compromise the two, so pathology must make up its mind more clearly as to what its objects are to be. It seems as if the future will see diverging lines of development and that we shall have a pathology that is really and sincerely medical, and a pathology of a more generalised type which is frankly biological in its outlook. The association of medical pathology with medicine is at present not close enough. So far, in spite of its drawbacks, it has never failed to attract some of the best students of our medical schools, but the infusion of vitalising principle seems to be essential in the near future if it is to continue to do so. A subject that is not well remunerated must offer other attractions if it is to compete successfully and maintain its existence. What is overshadowing pathology at the present time is its divorce from clinical medicine The subjects are admittedly too large for any one individual to engage fully in both pathological and clinical work, but it would be of unquestionable advantage to everyone—pathologist, clinician, and patient alike—if the mechanism for closer coöperation existed in every pathological unit. The laboratory should be a training ground for the young clinician; in serving an apprenticeship there he would gain experience of great value to himself, and in doing so would relieve the pathological staff of a part of the heavy burden of routine work which, with the time occupied in teaching, leaves scanty opportunity for serious research. There is, we think, little doubt that in institutions in which a period of service in the laboratory is looked upon as a normal preparation for a post on the medical staff medicine is found in its most flourishing condition. A pathological unit should be a meeting-place in which every aspect of a medical problem can be viewed and reviewed in the light of specialised knowledge of the processes of disease. The tentacles of the pathological institute should penetrate the wards and other departments of the hospital, and free access should be provided for the laboratory worker to bring his special knowledge to bear upon clinical problems. The whole matter is vital and generally agreed upon in principle, but the stirring to action is slow in coming. Much depends upon the creation of what is called in modern phrase a suitable atmosphere. Every member of the clinical staff should feel that it is not only his right but his duty to keep in personal touch with what goes on in the laboratory, and on their side the pathological staff must be allowed to slough the impeding tradition that their main purpose in life is to cut morbid specimens in the dead house. It must be an everyday and natural thing for them to enter at least some portion of the medical wards or out-patient departments where they may see disease in its active state. In a word, the pathology of the future must be compact, more of morbid physiology and less of morbid anatomy. The director of the pathological unit should have a guiding hand upon all the laboratories of the hospital, where there are more than one of these, and whilst remaining a whole-time pathologist might well have access to a certain number of beds, with facilities for investigating special types of case as the need arises. The recommendation made by the Carlill trustees that a few beds should be placed at the disposal of the director of the proposed pathological unit is a step in the right direction.

Improvements of this sort will do much for medicine, but they may put further off than before the prosecution of the more generalised study of pathology which Prof. A. E. Boycott urges elsewhere. For this some provision and encouragement are needed too; the contributions which it will make to medicine will be perhaps sporadic and scattered, but they will be none the less considerable than the daily help which medical pathology will give. Medicine has in the past found some of its best advances in fields without any obvious clinical relations, and schools of pathology in the science faculties of our universities will further medicine as well as biology and will do much to clarify the present unsatisfactory compromise of conflicting ideals.

MEDICAL EXAMINATION FOR LIFE ASSURANCE.

The medical problems of life assurance have formed the subject of careful study both in this country and in America. The transactions of the Assurance Medical Society, which was founded in London in 1893 as the Life Assurance Medical Officers' Association, constitute a striking record of the work done in this country. They are in effect a veritable encyclopædia of reference in regard to these problems, and to this encyclopædia a notable addition has just been made in the suggestive presidential address of Dr. G. Grahamsley Howitt. The history of life assurance and of the association of the medical profession with it is well worthy of study. The earliest appointments as medical advisers to insurance companies Dr. Howitt has been able to trace were made in 1823. The evolution of the medical report from its earliest simple type to its present form, which is essentially the same for most companies, has taken place largely during the last half century. Having commented on the origin and development of insurance medicine, Dr. Howitt proceeded to discuss some of the problems introduced by the employment of laboratory methods in the study of disease. This part of his address is published in abstract on p. 1047 of this issue of The Lancet. It will repay study by those concerned in the medical examination of candidates for life assurance. Dr. Howitt points out that the advances made by instrumental and laboratory methods in clinical medicine sometimes seem to raise fresh problems for the insurance medical examiner. He instances the electrocardiograph and the polygraph as examples of instrumental methods. These instruments have helped to demonstrate that some forms of cardiac irregularity are not of serious import, and have thus rendered certain sufferers eligible for life assurance with or without an extra who would formerly have been declined or heavily rated. The difficulty the insurance medical examiner is placed in is that he cannot as a rule obtain the information these methods are capable of affording, owing either to the expense or the time involved in their application.

As an example of the problems introduced by laboratory methods Dr. Howitt instanced glycosuria. Study of the blood-sugar curves before and after the administration of glucose have demonstrated that there is a form of glycosuria called renal glycosuria or diabetes innocens in which the utilisation of sugar in the body is not interfered with, but in which the renal "leak-point" for sugar is lowered. Such cases are comparable to the condition of functional, postural, or adolescent albuminuria, and, like it, they would seem to be risks assurable with a moderate extra or with some small form of rating, either by limitation of the period for which the assurance is granted or by limiting the payments to a given age. Unfortunately, our knowledge of renal glycosuria is of such recent date that no sufficient data are available to forecast the future of such cases. It is one of the insurance problems which is still sub judice. The difficulty of the examiner is, however, not only in the rating of such cases, but in their differentiation from more serious forms of glycosuria and from true diabetes. A blood-sugar estimation and sugar-tolerance test is an expensive and time-consuming process for which the companies will not at present pay. It is only when a proposer is willing himself to submit to and pay for such an examination that it is possible to get this counsel of perfection carried out. Failing this, the examiner has to be content with several examinations of the urine under different diets—an unsatisfactory and unconvincing procedure.

Advances occur in insurance medicine as in all other branches of medical science, though necessarily more slowly. In this connexion it is of interest to note the recent action, to which our Berlin Correspondent has called our attention, of the life insurance companies in Germany in regard to medical examination. During the inflation period the companies tried to reduce their expenses and dispensed with medical examination. When the currency was becoming stabilised, they were disinclined to resume the use of medical examination for fear of diminishing their business, owing to the possible objection of proposers to be examined. They therefore, not infrequently, gave policies on the statements of their agents. The result has been some expensive law suits by the companies and a distrust of the companies on the part of some intending insurers. The tendency, therefore, is for the companies to return to the old method, and to require medical examination once more. Insurance without medical examination has been tried in this country on a not inconsiderable scale by some companies, but very careful safeguards in the form of personal statements are required, and in cases of doubt medical examination is often insisted on. It is instructive to observe the results in the German experience. This would seem to indicate that careful medical examination, though not essential, is a valuable safeguard to the companies.

DR. LOMAX AND HIS CRITICS.

It will be remembered that Dr. Montagu Lomax was the author of a book, "The Experiences of an Asylum Doctor," which attracted considerable public attention, and resulted in the appointment of a Departmental Committee to inquire into the allegations therein made as to the mal-administration of the mental hospitals. This Committee, before which Dr. Lomax himself declined to give evidence, made its report, and Dr. Lomax almost immediately wrote a reply to it, but, for a reason which he does not state, delayed its publication for nearly two years; it now appears in the form of a pamphlet[1] of 48 pages, and in view of the fact that a Royal Commission is now deliberating on the administration of Lunacy Law (see p. 1019) is worth discussing in detail.

Dr. Lomax is an exceedingly able and convincing writer, more convincing, in fact, than the surprise which he affects at the interest excited by his book. But in this controversy he is employing a method which in the columns of a journal eventually calls for the editorial footnote that "this correspondence must now cease." The subject of his protest has been ventilated so thoroughly, and so much has been conceded, in practice where feasible and elsewhere in principle, by the authorities to whom he is opposed, that the outstanding points of difference consist, at least in part, of details as to facts, motives, and procedure which might well be composed in a single evening were Dr. Lomax to dine amicably with a member of the Board of Control. For example, no less than three pages in this reply are devoted to what can only be described as a quibble over the method of calculating recovery-rates, a quibble all the more irritating because the author himself confuses annual admissions with the total resident population of an asylum. He thereby evolves a *reductio ad absurdum* (including, by the way, an actual mistake in simple arithmetic) intended for certain statistics as to recovery-rates, which, however, recoils on the author himself. Again, in the observation in the Committee's report that "Dr. Lomax was the only medical officer who neglected to enter in the prescription book the quantity of croton oil he prescribed," he assumes the word "quantity" to refer to numbers of doses, although they had previously "laid stress on the fact that in my first six months of office I prescribed 253 doses." It can obviously refer only to the quantity of the individual dose, and the singularly puerile argument based on this misunderstanding serves no purpose but to call to mind the methods of a junior school debating society. Two questions of fact on which no outsider can form an opinion are the subject of similar treatment—the exact date at which the "exercise pen" at Prestwich was brought into use, and the existence or otherwise of a "quiet, melancholic patient" who is alleged to have been put "behind the table" with degraded dements. The usefulness of comparing the total quantities of sedative drugs used annually in different asylums is hotly denied, and the value of bromides in epilepsy questioned. The text is also adorned by frequent quotations from the *Asylum Workers' Magazine*, a periodical whose attitude to the work of the institutions staffed by its own subscribers seems hardly flattering. One of these (p. 35), which suggests the entire abolition of the Board of Control, is so foolish and discreditable that its reproduction by Dr. Lomax might be regarded as ill-advised even by his most ardent supporters. It is to be noted (p. 1) that Dr. Lomax characterises his own original charges against mental hospitals as "vague and unsubstantial."

The main issues, however, are these. The Committee found that certain of Dr. Lomax's criticisms were justified, and some were not. Those that were justified concerned such items as classified accommodation, diet, clothing, parole, exercise, and adequacy in numbers and training of the staff (at Prestwich). Everyone concerned with the asylum service knew that there was room for improvement in these matters at many mental hospitals. The Committee naturally reported that such improvements were desirable. As Dr. Lomax observes: "Of the 15 recommendations made by the Committee 13 were made by me in my book and in almost identical words." These improvements are, indeed, being generally, if slowly, carried out, as the financial stringency consequent on the war is relaxed; municipal finance is the key to the situation, and those local authorities who are able to find the money are getting the things done. It is outside the powers of committees, superintendents, and the Board of Control, against whom Dr. Lomax's attack is directed, to hasten these changes, except by "recommending"; if they are listened to, all is well; if they are not, they can do no more. But there were other charges in Dr. Lomax's book which the Committee characterised as "gross exaggerations" or "demonstrably untrue," charges of an exceedingly damaging nature as to the attitude and conduct of asylum staffs. These, unfortunately, he now repeats. "But perhaps one of the worst uses to which the locked cell is put is as a torture chamber, where the most horrible brutalities are often practised upon defenceless patients." No evidence is given in support of this allegation. "The idea that any patients, or even attendants, are allowed to *enjoy* the beautiful gardens and grounds by walking or sitting about in them may be dismissed as in most cases entirely illusory." This, and its context, mean that no effort is made to render pleasant the environment of the insane. "Suicides and escapes—those twin bugbears of the official mind—are in reality the expression of our callous and rigid administration, and the injustice of wholesale and indiscriminate restraint." This, and its context, imply that all suicidal tendencies are the product of ill-treatment. The average reader of such assertions as these must either disbelieve Dr. Lomax, or conclude not only that the medical officers and nursing staffs of our mental hospitals are utterly indifferent to the welfare of their patients, but that they deliberately ill-treat them, and withhold from them the means of promoting their recovery.

Now it is understood to be Dr. Lomax's object to improve the treatment of the insane. He must know well that this treatment can only be undertaken in the existing mental hospitals, and that in improving their conditions, and particularly in securing the coöperation of the patient in efforts at bringing about his recovery, public mistrust is one of the most serious obstacles with which they have to cope. The consequences of legitimate criticism on the public attitude must be accepted, but when a well-known writer with professional experience talks of "torture," "warders," and "prisons," he is making himself responsible for a type of public prejudice and hostility which will long hinder the progress for which he is ostensibly working. It is from this point of view, and not merely because they are grossly libellous on his own and the nursing professions, that the repetition of these disordered accusations is most regrettable. The fact is that the maintenance of an injured attitude on Dr. Lomax's part is entirely unjustified. The Committee's report was admitted on all hands to be an exceedingly fair and well-reasoned statement of the facts. His legitimate criticisms were freely accepted, and his wild allegations of abuses were investigated with a patience, and reported on with a moderation of language, which perhaps they hardly deserved. It would have been more graceful on his part, and very much more useful for the public welfare, if Dr. Lomax had made some acknowledgment of the work of the Committee, for whose long and gratuitous task he was solely responsible, and had coöperated in promoting the future welfare of the mental hospitals by ceasing his attempts to prejudice the public against their administrators. Instead he abuses the Committee, and flatly accuses it of prejudiced selection of witnesses and the suppression of evidence. Perhaps

[1] A Reply to the "Report of the Committee on the Administration of Mental Hospitals," 1922. By Montagu Lomax, M.R.C.S. National Society for Lunacy Reform, 32, Avenue Chambers, London, W.C. 1. 1s.

Dr. Lomax has not heard that one of the principal witnesses who made allegations of ill-treatment at the inquiry has subsequently recovered completely, and has gratified the superintendent of the hospital in which he was confined by an entirely unexpected letter acknowledging that the ill-treatment of which he complained had never taken place.

◆

GENERAL MEDICAL COUNCIL ELECTION.

The Scottish and Irish Direct Representatives of the medical profession on the General Medical Council have been re-elected without opposition. Sir Norman Walker issued no election address; after 18 years of service on the Council he hardly needed to do so. The position of the Direct Representative is very different now from what it was in the early days, for the work of Executive and Penal Cases Committees is mainly done in camera; but Sir Norman Walker's service on the Examination Committee is there for all to read in the published reports, and it is owing in no small degree to his tactful pressure that clinical examinations in midwifery and gynæcology have been introduced by most licensing bodies. His hand will be also manifest in the interim report on anatomy and physiology to be presented at the forthcoming session of the Council. In many ways he has been a good friend to practitioners, and not in Scotland alone. Dr. Leonard Kidd has already served the Council for 19 years, and his presence there will be specially valued at a time when the old relations of Irish medical practitioners to the British Register and General Medical Council may be profoundly altered by hasty action.

The election of Direct Representatives for England and Wales is keenly contested as there are ten candidates for the four seats. Voting papers, posted on Nov. 12th, must be returned by Thursday, Nov. 20th. The four nominees of the British Medical Association—Dr. R. A. Bolam, Dr. H. B. Brackenbury, Dr. J. A. Macdonald, Sir Jenner Verrall—are all well known to practitioners in the country. Dr. Macdonald and Sir Jenner Verrall have already sat for a dozen years on the Council and have served on a number of its Committees. Dr. Bolam, who has shown executive ability of the highest order in the Association, has occupied a seat on the Council for six years, and Dr. Brackenbury's claims to the suffrage of his fellow-practitioners are too evident to require mention. They have all given practical evidence of tireless effort for the credit and welfare of the profession. The four nominees of the Medical Practitioners' Union—Dr. H. J. Cardale, Dr. H. F. Devis, Dr. E. A. Gregg, Dr. Gordon Ward—are men whose work has brought them closely in contact both with fellow-practitioners and with various State departments of medicine. Collectively, they stand for the view that in many directions medical education is unsuited for the requirements of the general practitioners, who form the bulk of the profession, and their plea is cogent that the weak points in the education of the future doctor can be best appreciated by those who are themselves engaged in general practice. The two independent candidates are Dr. John Brown, of Blackpool, and Dr. F. H. Westmacott, of Manchester. Dr. Brown would alter the National Insurance Act so as to restore the "ideal family doctor," and he would change the medical curriculum to make its keynote the prevention of disease. Dr. Westmacott stands as a consulting surgeon and teacher with wide experience of the requirements of medical education, as well as of the needs of the public. He possesses also an intimate knowledge of the education and practice of dentistry and of the requirements of the combatant medical services.

The choice set before practitioners is not easy, but it is an excellent thing that once in five years they should thus be brought to think carefully of the functions of the General Council of Medical Education and Registration and have to express their views as to what kind of representative they desire to send to sit on this Council.

Annotations.

"Ne quid nimis."

THE ORIGIN OF FOOT-AND-MOUTH DISEASE.

It is said that if you plant a row of empty bottles upside down in your garden they will presently be occupied by healthy little ferns, which shows that fern spores are universally present and will manifest their presence if anywhere suitable conditions are provided for their development. The epidemiology of foot-and-mouth disease suggests that the virus of that elusive disease is in much the same position as the fern spores and that it is local conditions which determine the outbreaks of the clinical malady. It is possible, however, that it is really carried about by some moving agent—perhaps by man and his belongings, perhaps by birds—and any attempt to explore the possibilities of this is welcome. Prof. J. M. Beattie and Dr. D. Peden, of Liverpool, bring forward evidence in the last number of the *Journal of Pathology and Bacteriology* (vol. xxvii., p. 415) implicating rats. They show in the first place that feeding or inoculating rats with lymphatic glands from cows slaughtered because they had been in contact with declared foot-and-mouth disease can give rise to an affection characterised by œdematous swelling of the feet and vesicles and ulcers on the feet and on the tongue, and that this can be transmitted from rat to rat in series. From their observations it seems fairly clear that rats can be infected with the disease. In a proportion of these rats they also observed areas in the lung—solid, yellow, rather translucent—which they describe as gelatinous œdema. Examining carefully the wild Liverpool rats which are regularly dissected in connexion with possible plague, they found this lung condition in about 2 per cent., and they show that the places where these animals were caught are suggestively related topographically to slaughter-houses and places which had certainly had contact with infected cows by means of the sewers. Inoculations from these sewer rats supposed to be suffering from foot-and-mouth disease did not succeed in infecting fresh animals, and it must be admitted that the case for the wild rats having foot-and-mouth disease at all is not strong. A lung condition, not obviously dissimilar from that described, is known to occur both in wild rats and in many laboratory rats after their first youth, and Prof. Beattie himself does not regard the association which he describes as beyond doubt. However that may be, the fact that rats are susceptible to foot-and-mouth disease (first published in The Lancet, 1924, i., 221) is important and suggestive, especially in respect of the persistence of infection in a locality. It is only under very exceptional circumstances that rats migrate or are carried over long distances, and their possible function in causing widely separated outbreaks in cattle is still more problematical.

THE EDUCATION OF MENTALLY DEFECTIVE CHILDREN.

The education of mentally defective children presents problems of considerable interest to the general public, to medical practitioners, and to the members of local education authorities. In urban areas special schools are provided for those defectives who are able to derive reasonable benefit from attendance thereat, but in rural areas the numbers in any village are too small to allow of the formation even of a special class. The only method then available is the establishment of a residential school; this, however, leads to difficulties in that many parents object to the children leaving home and that the expense per head is considerably greater than in the case of day school education. In towns where there are special day schools the difficulties are of another character. While it is generally recognised that all but those of the lowest mental grade can be improved, at least in habits, there are many who need entirely individual care, cannot coöperate in any of the forms of class work which are essential in a school, and disturb the progress of the other pupils by their erratic behaviour. The Education Acts have therefore, rightly, limited admission to special schools to those who are able to learn to control themselves and who are susceptible of class instruction; in other words, imbeciles are not eligible for admission. It has been realised that some provision of occupation for the children thus excluded would be desirable. The present position is, then, that in the rural districts there are children who need special education which is not available, while in both rural and urban areas there are those who could not be instructed in classes. The Board of Education recently, in Circular 1341 (The Lancet, Sept. 27th, p. 666), drew the attention of local education authorities to the importance of the problem; the Central Association for Mental Welfare now supplement this by a memorandum, pointing out how their local branches can help in the solution. They are prepared to help in the following ways:—

1. By friendly visits to the home by those capable of advising parents as to the methods of training or controlling the child and also by teaching simple handicrafts or manual occupations which will excite the interest of the defective child and prevent further deterioration from sheer inertia.
2. By inquiring into the possibilities of employment after the school age.
3. By providing occupation centres for young defectives who have perforce been excluded from ordinary or special schools or who after the elementary school age are unable to be employed in ordinary industries but are capable of learning some simple handicraft.

The training in these centres is of the simplest nature: Control in conduct and social relations, domestic work, simple manual work, singing, and dancing games. To a very large extent each child may occupy itself with such tasks as he feels inclined, thus allowing of progress along any line of interest. He is not so confined to his place as in school, though he gradually learns the advantages of order, and finds that without it he cannot join in games with others. Some 50 such centres, open five half-days a week, are already established and are doing most successful work. In some cases they have prepared the way for the admission of a child to a special school by accustoming him to coöperate harmoniously with others. The local mental welfare associations work under the direction of the responsible officers of local authorities, and by coöperation with local mental deficiency authorities ensure the absence of overlapping and continuity of care for the individual defective from childhood onwards. There can be no question of the great advantage such centres and home visits provide for the defectives and their parents, while reducing in early life the need for institutional care, which is not only costly, but is a source of sorrow and anxiety to the parents.

BLOOD PLATELETS IN FATIGUE.

Recently Dr. S. Caccuri[1] has published some interesting observations on the intimate connexion between the platelets and coagulation of the blood in the human subject after severe exertion. Eight individuals, almost all young and in good physical condition, were subjected to severe exertion by means of the ergostat for 40 minutes to an hour or even more according to individual resistance. Previous to the experiment a count of platelets was made and the time of blood coagulation noted; these observations were repeated immediately on conclusion of the experiment, and after 6, 24, and 48 hours. For the platelet count two methods were used, that of Giudiceandrea and of Aynaud; the technique for blood coagulation was that of Vierordt. It was found from these experiments that immediately after exertion there was a marked diminution in the number of platelets to the extent of one-third or even one-fourth. This plastrinopenia was not of long duration, and, in fact, in six hours was much reduced, and after 48 hours had returned to normal or given place to a definite increase (plastrinosis). At the same time there was delay in blood coagulation. The interpretation of these phenomena may be either a destruction of platelets or their unequal distribution. Plastrinopenia occurs in lymphocytic leukæmia, pernicious anæmia, and anaphylactic shock, and in these conditions abnormal forms of platelets are found, but after severe exertion only those in a complete state of development are met with, and this fact seems to indicate that instead of a destruction, a migration of platelets from the periphery to the deep organs occurs. The probable explanation is that fatigue liberates into the circulation harmful products, which influence in various degrees the different organs; and the blood resents this harmful action. As the toxins must be neutralised by antitoxins, it is especially the organism, not habituated to excessive exertion, which is incapable of a prompt and sudden reaction when taken unawares by their abnormal increase. When after 24 hours the organism is in repose and has been able to eliminate the refuse and the toxins are completely neutralised, and when the period of repair has begun, then the platelets return to the general circulation from the internal viscera together with those produced by the hæmopoietic tissues by a process of secondary reaction. The simultaneous change in the time of blood coagulation also shows the intimate connexion between the platelets and this physiological phenomenon.

AMŒBIC ABSCESS OF THE LIVER.

Amœbic abscess of the liver is a relatively uncommon condition in this country, and for that very reason is apt to escape suspicion as being the cause of chronic illness associated with fever. The diagnosis is sometimes quite clear because of the very pronounced enlargement of the liver, but sometimes obscure owing to the situation of the abscess high up in the right lobe of the liver under the diaphragm, where it is not easy to reach even with an exploring needle. The rare abscess in the Spigelian lobe cannot be revealed by puncture owing to its situation. A small abscess in the left lobe also may defy diagnosis for a long time. Since the disease in this country is rare, no single surgeon can have extensive experience of it unless he has lived abroad. He must, therefore, be guided in his treatment of such cases as fall under his care by the experience of those practitioners who constantly have to deal with dysentery and its complications. In another part of this issue Lieut.-Colonel E. Owen Thurston reports results of his treatment of 64 cases of liver abscess. All these occurred in Indians except one. There was no history of dysentery in one-third of the cases—a point to bear in mind in the differential diagnosis of enlargement of the liver. More than two-thirds of the cases—49—were treated by aspiration alone, and of these 40 recovered; four cases were aspirated and later drained when this proved ineffective, and nine were treated by incision and the cleaning out of the abscess cavity with gauze, followed by complete closure of the abdomen. All these cases recovered. There are three methods of treating liver abscess: open incision and drainage, aspiration, and the evacuation of the abscess cavity by a laparotomy, with subsequent closure without drainage. Aspiration alone is effective in a large proportion of cases, and is apparently the method of first choice. The author insists that it is necessary to give at the same time a large dose of emetine. He believes that open drainage should scarcely ever be necessary. It must be remembered that the diagnosis is not always certain before laparotomy. This is especially likely to be the case where the disease occurs in the European, who seeks help far earlier in the course of the illness than does the native Indian. Sometimes, too, as mentioned above, the abscess is in a situation inaccessible to the needle. For these patients the third method has many advantages. It allows of complete exploration of the liver and gets rid of the pathological contents of the abscess cavity, whilst there is no danger of secondary infection occurring through an open drainage-tube. Emetine should be given at the same time. The open drainage operation is only indicated where it has been definitely proved that the infection is a mixed one. Amongst those surgeons who have had large experience of liver abscess and the treatment of dysentery by emetine, there seems to be a difference of opinion as to the possibility of an abscess of the liver, of any size, completely absorbing. In the *Indian Medical Gazette* for October, 1924, Captain A. Sargood Fry reports two cases of large abscesses, demonstrable by X rays, in the right lobe of the liver, in which the clinical cure of both patients, with complete absorption of the abscess, was effected by the administration of emetine hydrochloride hypodermically alone. He is of opinion that aspiration can in many cases be dispensed with, and he thinks that the spontaneous absorption of a large sterile abscess has no injurious effect upon the patient's health. Demonstration of the cure of those two patients without the aid of aspiration is interesting, but it may be doubted whether, as a general rule, it is advisable to withhold the assistance which aspiration affords to the obliteration of the abscess cavity. Aspiration has another advantage. It reveals those cases which, because of a secondary septic infection (14 per cent. of all abscesses), call imperatively for open incision and drainage.

LESSONS FROM RAT METABOLISM.

THE science of dietary is at the present time very much in its infancy, and there is a great need for further experimental work on nutrition. There is especially a lack of data with regard to suitable food for the nursing mother, the evidence at present available being conflicting. Experiments on animals are of direct value to the dietitian in so far as the principles of animal nutrition are applicable to human beings, and in the September issue of the *American Journal of Hygiene* Miss Nina Simmonds published the results of her investigations into the influence of diet on reproduction and rearing of young by the rat. The recorded data regarding growth and reproduction are based on experiments extending over nine years. Feeding experiments to be of value must be continued for long periods and should involve more than one generation; the fertility and nursing records are a much more sensitive test of a ration than is the growth curve. Miss Simmonds finds that the mammary gland in the rat cannot synthesise certain substances necessary to the well-being of the young—e.g., the amino-acid lysin, vitamin A and vitamin B (apparently the rat does not need vitamin C). "The nursing mother cannot, except in a very limited degree, put into her milk from her bodily reserves that which she does not receive in her food-supply." The experiments show that a high protein dietary during lactation does not interfere with the growth of the suckling. In fact, beneficial effects are quoted as a result of giving the mother rat a diet relatively rich in protein, although such a dietary does lead to progressive kidney degeneration with loss of function. Hartwell,[1] [2] however, on the other hand, finds that a diet rich in protein leads to an abnormal condition of the young, producing spasms and other morbid manifestations which frequently result in death of the offspring; she also demonstrates that these evil effects can be remedied by giving the mother rat a *large* amount of vitamin B—i.e., far more vitamin B than is necessary for the non-lactating animal. Simmonds comments on the supplementary value of certain proteins; for example, muscle protein is a good supplement for the protein of wheat and rolled oats, whereas liver or kidney protein proves more satisfactory when fed with rye and wheat proteins. A combination of the proteins from cereal grains and legume seeds is not a good one, at any rate from the point of view of reproduction. If a ration be low in calcium, the addition of cod-liver oil to such a diet enables the rat to utilise the calcium more efficiently than does butter-fat. Provided that optimal amounts of calcium and phosphorus are present in the diet, cod-liver oil has no superiority over butter-fat. A diet poor in calcium results in sterility; fertility can be induced by adding cod-liver oil to this diet; the rat can then rear her young, but at the expense of herself, for she loses calcium from her skeleton, and will collapse after rearing one or two litters. The superiority of cod-liver oil over butter-fat in this respect is due to the fact that cod-liver oil contains more of the factor concerned with bony growth than does the butter-fat. Simmonds seems to aim at finding one diet which is entirely suitable for all periods of life, while Hartwell [4] maintains that the periods of growth, gestation, and lactation probably have separate needs from a nutritional point of view. Mitchell,[6] in his paper on the nutritive value of proteins, states that the biological value of proteins for growth is a different problem from the biological value of proteins for maintenance, and further, that the conditions of gestation and lactation also call for separate investigation. We notice that Simmonds finds that it is only to within a very limited degree that the mother sacrifices her bodily reserves, yet Korenchevsky [5] states that the maternal organism will sacrifice her own tissues as far as possible for her offspring. Hartwell [2] has shown that a nursing rat which is receiving a badly balanced diet can lose as much as one-third of her body-weight in ten days. Simmonds' paper is an excellent survey of her own far-reaching experiments. They have yet to be brought into proper relation with the work of others in the same field.

THE CAUSE OF DEATH IN MALARIA.

WHAT are the pathological conditions which bring about a fatal issue in malaria? Dr. C. Seyfarth, of Leipzig, has set himself to answer this question.[*] Between 1916 and 1918 he conducted 200 post-mortem examinations on fatal cases of malaria occurring in the severe epidemic in the Balkans, when much work was done by various pathologists, whom he quotes. In his consideration of the causes of death in malaria he leaves out of account cases where the patients, after a prolonged history of malarial cachexia, died of some intercurrent disease. Death in acute malaria may occur very suddenly, and is often puzzling to the pathologist, sometimes being ascribed to apoplexy, heat-stroke, or even to dysentery. Dr. Seyfarth differentiates seven causes of death as follows: 1. Septicæmia, which he states accounts for 30 per cent. of the total deaths in malaria. It is due to massive infection, when severe bodily hardships have reduced resistance and permitted an incredibly rapid numerical development of the parasites, so that one, two, or more are found in each red cell. In few cases does complete development of the parasite occur; toxæmia sets in, with coma and heart failure as sequelæ. Post mortem there is little pigmentation or other change in the internal organs. From such toxæmic cases must be distinguished those with parasitic embolisms in all or several organs. These latter cause the various clinical forms of pernicious malaria such as cerebral and pneumonic, and are due especially to the subtertian form. The emboli lodge in the capillaries of the central nervous system, in those of the heart, kidney, pancreas, or suprarenals, and can be found there post mortem. 2. Cerebral involvement causes 55 per cent. of the total deaths. Here there are few parasites in the peripheral blood, but they are found in quantity in the brain, which may show punctiform hæmorrhages. 3. Cardiac complications account for 14 per cent. of the total deaths. These cases, when syncope occurs, often end very speedily. Death is due either to specific embolism of the coronary arteries, or to toxic causes with myocarditis or fatty degeneration of toxic origin. 4. Renal complications are responsible for about 1 per cent., emboli causing extensive tubulo-glomerular nephritis. 5. Suprarenal involvement has lately been noted as a cause of death several times by French observers. 6. Acute hæmorrhagic pancreatitis may be set up. 7. Rupture of the spleen. In the course of this complication the patient has a most severe abdominal attack, the spleen swells, the capsule becomes thinned and ruptures spontaneously or after some slight injury, and death is due to hæmorrhage. These seven classes can generally be distinguished after death, but sometimes with difficulty only, and they occur, not only in acute first attacks, but in the flaring-up of chronic cases. With regard to malarial cachexia, Dr. Seyfarth states that death is very often due to some condition introduced subsequently, such as infectious diseases or scurvy, beri-beri, and the like, but many cases with the severest anæmia and bone-marrow change die of portal thrombosis. A. Bignami and others also mention a malarial-waxy condition which may cause death. It must be kept in mind that not only in malarial cachexia but also in both acute and chronic malaria secondary infections may be the cause of death. Of these secondary infections the author found the most frequent to be broncho-pneumonia, dysentery, especially bacillary dysentery, strepto- or staphylo-coccal septicæmias, and ulcerations, in particular gangrenous ulcerations. Further ordinary attacks of infectious disease are apt to reawaken chronic malaria, and in malarial districts appearances characteristic of malaria are sure to be found in the body of a patient dead of any disease whatever.

THORACOTOMY OR ASPIRATION.

THE serious mortality following operative treatment of empyema, especially in small children, has been a matter of concern to the medical profession for many years. Last year a considerable amount of light was thrown upon the nature of this mortality by H. C. Cameron and A. A. Osman (THE LANCET, i., 1923), who showed that the cases which were treated by rib resection during the course of the pneumonia usually died, while those treated after resolution was complete usually recovered. At a recent meeting of the Liverpool Medical Institution, reported elsewhere in this issue, Mr. Thelwall Thomas emphasised the necessity in severe cases of empyema complicated with pneumonia of repeated aspiration before resorting to incision; and in *La Vie Médicale* of Oct. 23rd, 1924, Dr. Ribadeau-Dumas and Prof. Rocher deal with this question. Their opinion with regard to prognosis coincides entirely with that of the authors quoted above, and they deprecate any form of thoracotomy in cases of parapneumonic empyema, or of children in the first two years of life, preferring the removal of pus by aspiration or siphon drainage until resolution in the lungs is complete. Their views on the treatment of metapneumonic empyemata are more conservative than those of the majority in this country; their principal object is to avoid the entrance of air into the thorax, and they consider that intercostal thoracotomy with a minimal opening into the pleura usually yields as good a result as resection of rib, and is the method of choice in most acute cases. This conservative tendency will not be found in the article in which Dr. Carl Hedblom [1] reviews the treatment of non-tuberculous pulmonary suppuration. He considers that the treatment of pulmonary abscess depends mainly on the localisation; if the abscess is central, bronchoscopic lavage or artificial pneumothorax may be of benefit, but the central abscesses are likely to heal spontaneously. Peripheral abscesses should be drained unless the patient is definitely improving under medical treatment. Having shut off the pleural cavity by a two-stage operation, or by suture, he locates the abscess by means of the exploring needle, and burns a tract to the abscess, with the needle still in place, leaving a wide open drainage of the cavity. Should exploration fail to localise the abscess, a tract is burnt to the suspected area and packed, since the abscess may burst into this tract later. For a long-standing chronic abscess he recommends cautery lobectomy as affording the best chance of cure, but admits the danger of fatal hæmorrhage. In discussing the treatment of bronchiectasis he states that in localised forms drainage causes very marked improvement as long as it is kept open. For unilateral diffuse cases he performs an extrapleural thoracoplasty in five stages, accompanied by alcohol injection of the intercostal nerves. Pneumothorax collapse may be used as a test of suitability, if it is followed by relief of symptoms the extrapleural operation is indicated.

NEGLECTED CORNERS OF OTOLOGY.

Dr. J. Kerr Love, who presided at the Otological Section of the Royal Society of Medicine on Nov. 8th, made the striking statement that there had been scarcely any appreciable advance during the last 50 years in the cure of deafness—he was not speaking of surgical treatment. It was only recently that orthodox medicine was making any effort to prevent deafness, and in consequence the management of cases of chronic deafness had been left largely in the hands of the empiricist and the quack. Much deafness was due to infectious disease of the throat, and the more thorough treatment of enlarged tonsils and adenoids was already limiting the otologist's activities. One neglected corner of the otological field was certainly in the hospitals for infectious disease, for otologists were rarely appointed to their staffs. Speaking for Glasgow, he was not aware of any aural specialist attached to the fever hospitals with several thousand beds. Many fever patients still had discharge from ear or nose when they left the hospital. Another neglected corner Dr. Love finds in institutions for the deaf, which may have on their staff a physician, an ophthalmologist, an odontologist, a dermatologist, but no otologist. Deaf-mutes with middle-ear suppuration may require adenectomy to restore their health, although it cannot restore their hearing. Such institutions possess a store of clinical material which may be used for elucidating problems such as the influence of syphilis on congenital deafness. Dr. Love does not go as far as French authorities, who ascribe 25 per cent. of cases of congenital deafness to inherited syphilis. He places the upper limit at 10 per cent., but strongly holds that the effect of syphilis on the ear may extend not merely to the third generation, but beyond it. He does not regard a negative Wassermann as disproving the syphilitic origin in any particular case. Apart from this, the otologists, Dr. Love thinks, have not made the most of their opportunity in guiding the public in the matter of aids to hearing. He hoped some physicist would be found to make practical use of the fact that many subjects of middle-ear disease hear best in a noise. Unfortunately, many children did not respond to electrical aids; in a test which he had instituted at the hands of good teachers with abundant opportunity, out of 60 children tested only four definitely benefited. Dr. Love's review covered the whole period of his own recollection and deserves wide attention.

RICHARD OWEN AT THE HUNTERIAN MUSEUM.

IN his Vicary Lecture, delivered at the Royal College of Surgeons of England on Nov. 12th, Sir Arthur Keith throws interesting light on the almost constant conflict between Richard Owen and the Museum Committee during his tenure of the office of conservator. Hunter had pursued his studies and built up the museum to throw light on man—on the nature of his disorders and diseases and on the manner in which the functions and actions of his body were accomplished. He knew well that the collections he had assembled might be employed for two other purposes. His dissections might be used, not for the study of function but for the classification of all living things into natural groups and orders. He knew that his great collections of fossils opened vistas into past ages of the world. Hunter turned his back on such aims, but two years after his death Cuvier set to work. He built up anatomical collections just for the two purposes which Hunter refused to entertain, and by his genius and industry enthralled the world by his discoveries during the first three decades of the nineteenth century. At first Owen's sympathies were with Hunter's original aims, but they soon became dissipated under the brilliance of Cuvier's sun. When Cuvier visited the Hunterian museum in 1830, a few months before his death, he fired young Owen with his aims and zeal. In Owen's time the Natural History Departments of the British Museum were in abeyance, and Owen set out to make the Hunterian museum supply a national deficiency. He intended it to be the home for the classification of all forms of animal life, for the separation of the animal kingdom into natural groups according to structure. More particularly he intended that the museum should become the headquarters for the interpretation of past worlds of life. If, Sir Arthur Keith concluded, we are to understand the continual friction recorded throughout Owen's time, it is necessary to keep in mind the clash of ideals—the ideal the Museum Committee had in view and the ideal which Owen nursed as if it were his religion. The committee was for ever trying to get Owen to go its way, and he was for ever breaking off to follow his own path. It was in Cuvier's world that Owen lived, not John Hunter's. To study structure and function as a service to medicine we must, in Sir Arthur Keith's words, "go back to Hunter."

---

[1] Minnesota Medicine, vol. vii., No. 10.

The fifth British Congress of Obstetrics and Gynæcology will be held in London at the Royal Society of Medicine from April 22nd to 24th, 1925.

The next session of the General Medical Council will commence at 2 P.M. on Tuesday, Nov. 25th, when Sir Donald MacAlister, the President, will take the chair and give an address. The Council will continue to sit from day to day until the termination of their business.

The King has approved of the award this year by the President and Council of the Royal Society of a Royal Medal to Dr. H. H. Dale, F.R.S., for his researches in pharmacology and physiology. The Copley medal has been awarded to Sir E. A. Sharpey Schafer, F.R.S., for his work on physiology and histology. The Darwin medal has been awarded to Prof. T. M. Morgan, Foreign Member, R.S., for his work in zoology, especially his researches on heredity and cytology.

The death of Dr. John Tatham at the advanced age of 81 years removes a great figure in medical statistics, for he was during the active years of his life Superintendent of Statistics at the General Register Office, and his Supplementary Reports on the Mortality of England and Wales and on English Occupational Mortality are works of classical importance. Dr. Tatham's apprenticeship to public health work was served at Salford and Manchester in the 'seventies and 'eighties of last century. A biographical notice will appear in a later issue.

Heritage Craft Schools.—The new wards and operating theatre have now been equipped at the Heritage Craft Schools at Chailey, in order that the necessary orthopædic work amongst the cripple boys and girls in the institution may be carried out on the spot and thus secure the continuity of treatment and education which has proved of such value in these cases.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XCVI.

THE TREATMENT OF ACUTE OTITIS MEDIA.

Acute otitis media, when attacked promptly and with particular care in the after-treatment, is comparatively easy to deal with, and a complete cure with perfect hearing, although it cannot be promised, is a reasonable probability. On the other hand, chronic suppurative otitis media is intractable, and the prospect of obtaining even a healed membrana tympani is doubtful; moreover, such healing, if obtained, rarely restores good hearing. Meanwhile, the patient suffers a continuous deterioration in general health, besides incurring a constant risk of dangerous complications. Obviously, no trouble is wasted if it may prevent the acute merging into the chronic condition.

Prophylaxis.

The liability of everyone at all times to an ascending Eustachian infection is greatly increased by sepsis in the nose or throat, or their annexa. And the timely correction of pyorrhœa, nasal turbinal hypertrophies, or nasal accessory sinusitis greatly reduces the actuarial probability of such infection. In children the most frequent predisposing cause is found in septic tonsils and adenoids, especially the latter, which, in suitable cases, may be removed without interference with the tonsils. In brief, prophylaxis comprises the toilet of the mouth, nose, and post-nasal space. But supposing that despite, or in the absence of, these precautions a patient arrives suffering from what seems to be acute otitis media, it is to be remembered that an intolerable boring pain, which has no respite, may be caused by other conditions than acute otitis media, of which it is so characteristic. I refer chiefly to meatal furunculosis and to old impacted wax which has suddenly swelled with moisture; either of these may coexist with an acute middle-ear infection. Again, with almost identical physical signs in both drum-heads, the pain on one side may be so great that no complaint at all is made of pain in the other ear; thus, in order to avoid a second and superfluous anæsthetic, both drums should be inspected.

Having decided that the condition is, in fact, an effusion into the middle ear, the further point at issue is whether this effusion is catarrhal or purulent; that is, whether the drum calls for an immediate incision or not. In those cases where the physical signs indicate only a catarrhal condition, and pending arrangements for operation in the suppurative cases with which this article chiefly deals, an expectant attitude should be adopted.

Expectant Treatment.—Local analgesics give great comfort. It is usual to employ glyc. ac. carbol. 1 in 10 to 1 in 5; or "Ovoids" containing opium or cocaine, made by Messrs. Savory and Moore. A cholagogic purge is essential, preferably calomel.

Operation.

Pus, once diagnosed—in a stereotyped case by a loss of landmarks in an opaque membrane, which, over a part or the whole of its extent, shows a bulge of which the colour varies from yellow, through salmon-pink, to an angry red—must be released. Myringotomy may be performed under a prolonged nitrous oxide anæsthesia, or gas and oxygen, or a light ether narcosis. The incision may reveal only a bead of pus, and this may be obscured by blood, although the hæmorrhage is insignificant. It is imperative to operate, because, first, the middle layer of the drum-head consists of radial and circular elastic fibres, and after a clean incision fewer of these (especially the radial) are severed than if the membrane be allowed to burst; in the former case the opening is less ragged, so that rapid and complete healing is more probable. A second reason for early incision is that before rupture occurs the infection may spread not only to the mastoid, but to the meninges or brain. At the conclusion of the brief anæsthesia, and as soon as the ear has been covered up, the patient, if young, should be digitally examined for adenoids, if this examination has not been previously made. If any are found, their removal should be postponed, for the creation of a raw post-nasal area at this time might spread or maintain an infection, so that a unilateral case might become bilateral, and even in a case already bilateral healing would be invalidated.

After-treatment.

Immediate After-treatment.—Meticulous care in this, including a strict antiseptic ritual for the first ten days, will be well repaid. From one of the various firms who cater for surgical equipment a tin containing six packets of aural dressings should be obtained; also, if the patient be a restless child, a "mastoid cap," which is less liable to displacement than is an ordinary bandage. Circumferential hair should be cut sufficiently short to prevent any stray hair from wandering into the concha. At the close of the operation a wick, about five inches long, of plain sterilised woven-edged ribbon gauze, not more than three-quarters of an inch wide, should be inserted into the meatus for half an inch; the surplus inches of gauze are loosely folded into the concha. Subsequently, the wick is changed every 24 hours; and each day before replacing the wick the meatus is gently wiped out with a piece of similar ribbon gauze made just moist with lot. ac. borac. 75 parts, spir. vin. rectif. 25 parts, and two or three drops to the ounce of tinct. iodi. After two or three days there is a tolerance to the warm sensation produced by the alcohol, which may be gradually strengthened up to 40 per cent. These manœuvres are facilitated by gently pulling the pinna backwards, thereby straightening out the curve in the cartilaginous meatus and rendering access more direct. Quite possibly no pus will ever be seen, even on the first dressing; the drum-head heals by first intention, and is intact in a fortnight or less. The friable healed area would be easily reopened by slight trauma or sepsis, and it is wise to keep a very light wick in the ear for another fortnight. After three months it may be difficult to find a scar. It is not desirable to syringe the ear at this stage.

Remote after-treatment differs according to the course of the case: whether (*a*) favourable (fortunately common) as heretofore outlined, or (*b*) unfavourable.

(*a*) *Favourable Cases.*—An alkaline nasal douche, in all patients old enough to use it, should be instituted as soon as acute symptoms cease, and continued twice daily for six weeks. In small or intolerant children a spray should be substituted. After two months the membrane is strongly healed, and then, but not sooner, if slight deafness or tinnitus remain, the mobility of the drum-head should be simultaneously examined and encouraged by using a Siegle's speculum, which provides a feeble form of air-massage. More vigorous movement may be required, as supplied by a pump attached to an electrical motor of the Pantostat type. And, to complete the cure, a few inflations with the Eustachian catheter may be most helpful of all. Any adenoids should be removed, and, if septic, the tonsils also by dissection, as a precaution against recurrence.

(*b*) *Unfavourable Cases.*—Suppose that during the first few days pus, instead of being absent, persists or even increases, and at the end of a week there is still otorrhœa, with slight irregular pyrexia and perhaps trivial aching discomfort, it is clear that healing by first intention has failed, and, as in the case of any other wound in like condition, dry dressings no longer meet the case. Recourse must now be had to syringing, twice or thrice daily, but at first with only the most bland unirritating fluids. Warm lot. ac. borac. is the best, to which, as in swabbing out the favourable cases, alcohol may be gradually added up to 25 per cent. As useful alternatives warm aqueous solution of resorcin, 4 per cent., or of chinosol, 1 in 1000, may be tried. Under this régime the membrane may heal in another two weeks. If not, if the suppuration still continues, and the pus instead of becoming steadily thinner and more scanty remains yellow and so thick that its inspissation sometimes threatens to block its own egress, a stronger antiseptic is called for. An effective lotion is warm mercuric potassium iodide, 1 in 4000. There are various useful lotions and preparations for the treatment of obstinate otorrhœa, but their use, as also such methods as ionisation, belongs rather to the subject of chronic otitis media. If after using a lotion for three more weeks—that is six weeks from the onset of the infection—there is still no sign of healing, the possibility of chronicity must be faced. And here, as regards treatment, we are at the parting of the ways; two courses are available.

The first possible course is to temporise by using a vigorous cleansing agent such as hydrogen peroxide. This, despite its valuable properties, carries about, by the mere mechanical movements of its bubbles, any and everything which they loosen—including infected debris containing micro-organisms which have escaped destruction. In the early days, therefore, the infection may be spread by its use. Later, when a barrier of granulation tissue has shut off surrounding areas, hydrogen peroxide is a good friend. From the point of view of obtaining healing and good function, its use is an admission of probable defeat, implying that the case is already on the border-line of chronic suppurative otitis media, and as such passes out of the province of these notes. In some cases it is necessary thus to temporise with hydrogen peroxide, but in others there is an alternative.

The second course is to face the issue and apply the ordinary surgical principle of counter-drainage. In obstinate cases of recent acute suppurative disease counter-drainage by a tube placed in the antrum after a simple mastoidotomy is often the best course. The antral cavity, of course, becomes obliterated by granulation tissue which gradually becomes fibrous, and there is no consequent functional disability. The usual outcome is that an acute condition which threatened to become chronic rapidly ceases, with perfect healing, and—after perhaps a few subsequent Eustachian inflations—excellent function results.

If this more active method is to be pursued, it must not be long delayed. It should be considered in any case which obstinately persists for three weeks, and undertaken before the lapse of eight weeks.

H. LAWSON WHALE, M.D. Lond., F.R.C.S. Eng.,
Otologist to the Hampstead General and to the
London Temperance Hospitals.

ROYAL INSTITUTION.—Concerning the Habits of Insects is the subject of the ninety-ninth course of Christmas lectures to be delivered at the Royal Institution, 21, Albemarle-street, London, W. 1, this year by Mr. F. Balfour Browne, lecturer in entomology at the University of Cambridge. The first lecture is on Dec. 27th on Insect Collecting and What it Leads to, followed by the Habits of Bees and Wasps (Dec. 30th), Habits of Caterpillars (Jan. 1st), Habits of the Dragon-fly (Jan. 3rd), Habits of the Water-beetle (Jan. 6th), and the Habits of Insects and the Work of Man (Jan. 8th). The lecture hour is 3 P.M.

COLLEGE OF PHYSICIANS OF PHILADELPHIA: ALVARENGA PRIZE.—The Alvarenga Prize for 1924 has been awarded to Dr. Gordon Cameron, Victoria, Australia, for his essay entitled Pancreatic Anomalies: their Morphology, Pathology, and Clinical History. The next award of the Alvarenga Prize, amounting to about $300, will be made on July 14th, 1925. Essays intended for competition may be upon any subject in medicine, but cannot have been published. The essay should represent an addition to the knowledge and understanding of the subject based either upon original or literary research. Further particulars may be obtained from the secretary, Mr. John H. Girvin, 19, South 22nd Street, Philadelphia, Pa., U.S.A.

Special Articles.

MODERN MEDICINE IN EGYPT.

EGYPT is a land rich in historical associations with the science and art of medicine. Even before the time of Moses, one of the earliest of public health workers, whose account of what was known in his day of midwives and general hygiene is to be found in the Pentateuch, there were many deities who were supposed to preside over the cure of disease. Isis, Seraphis, Chonsu, and Thoth are amongst those who were worshipped as medical divinities. Later, with the birth of Hippocrates (460 B.C.) "medicine was separated from philosophy"[1] and treated as a more exact science in Egypt, and Celsus gives much information on the school of anatomy at Alexandria, which remained famous up till A.D. 300. Galen studied medicine in Alexandria about A.D. 150, and even when he settled in Rome he constantly urged students to visit that city, which was then the centre of the intellectual world. The first hospital in Egypt is said to have been built about A.D. 875. The Muristan was a remarkable institution established in Cairo in 1286, and even in recent times its ruins have been used as an eye dispensary. The Kasr-el-Ainy palace was turned into a hospital in 1799 and rebuilt in 1812; later it became the earliest government medical school in Egypt. With the occupation of that country by England a completely new school of medicine was established in it which still continues to be the centre of medical education and research in that country. Under imperial guidance public health work in Egypt has striven with manifold success "to combat a variety of diseases and solve a series of problems possibly without a parallel in any other part of the world, for Egypt shares in a large measure the pathology of both temperate and tropical lands."[2] With the withdrawal to a marked extent of this imperial guidance it seems an opportune moment for considering certain aspects of modern medicine in Egypt which have from time to time formed the subjects of papers contributed to these pages.

Anthelmintic Work.

During 1923 about 50,000 new patients attended the six special annexes which have been set up in connexion with the Kasr-el-Ainy Hospital, Cairo, and the hospitals in five other large towns.[3] Each of these annexes is a complete unit consisting of waiting-rooms, latrines, treatment rooms, clinical laboratory, and rest-shelters. The patients, of whom 70 per cent. are men, are examined from a general point of view and specimens of dejecta are obtained, and in this way all positive cases suitable for treatment are easily selected. Of these patients the great majority are infected with bilharziasis or ankylostomiasis. In the bilharzial cases antimony is used with marked success. Intravenous injections of antimony sodium tartrate are given, this treatment being carefully controlled by routine microscopical examination of the excreta, and no case is considered cured until living ova permanently disappear. If the patients attend regularly for injections, such a result is usually obtained after a course of 12 injections spread over four weeks, and only about 2 to 4 per cent. require a second course to ensure a cure. With careful selection of cases and with proper medical supervision during the period immediately following the injections, when the patients rest in the shelters, the treatment adopted seems to be remarkably free from danger. Emetine has also been used in the treatment of this disease, but it is too expensive a drug for routine purposes. In some districts intestinal bilharziasis is particularly prevalent, and the diffuse papillomatosis sometimes occurring in the rectum in this disease has been successfully treated in certain cases by complete excision of the affected mucous membrane. The constant tenesmus associated with the passage of blood and mucus condemns the patient to such a state of misery that even if this operation is attended by untoward results, such as stricture, which occurred in one of the eight cases recently reported,[4] the patient's condition is infinitely to be preferred to his previous state. A tube of as long as 17 inches has been successfully removed in one case and the operation offers a good chance of cure of this most distressing condition.

Ankylostoma cases form about 40 per cent. of the patients treated at the anthelmintic centres. Laboratory diagnosis is made as a routine despite the fact that severe anæmia is almost always due to ankylostomiasis in Egypt. The treatment adopted is the administration of carbon tetrachloride or oil of chenopodium, and this is continued until ova are no longer found in the excreta. As a rule, two treatments with the former or three with the latter drug prove effective. The anæmia resulting from this disease has also to be treated, and in severe cases due to this parasite or to bilharziasis blood transfusion is sometimes necessary. In connexion with this operation, which is also employed for primary anæmia and surgical shock and has been suggested for use in deficiency diseases such as pellagra, diabetes, and rickets, certain interesting points arise with reference to the compatibility of the bloods of the various races in Egypt. "There appears to be perfect mutual agreement between the transfused blood of Negro, Negro-Arab, Egyptian, and Levantine races, as well as that of fair-haired Turks or Circassians."[5] The proportion of Group IV. donors is low as compared with Europe, and it is believed that the parasitic diseases occurring in Egypt may be responsible for a modified positive Wassermann reaction in certain cases, making the selection of suitable donors somewhat complicated.

Rabies.

To the Kasr-el-Ainy Hospital in Cairo are brought about 2000 cases of animal bite a year and about 15 of these cases develop hydrophobia, consequently affording a remarkable opportunity for the study of this disease.[6] Rabies is endemic among the dogs, jackals, and desert wolves in Egypt, and while the incidence of this disease among camels is low, these animals produce the worst bites and constantly figure in the statistics. The latent period of the disease appears to be, on the whole, shorter than has been reported from other parts of the world, and while it is believed that less than 1 per cent. of cases bitten by all animals develop rabies the difficulty of establishing statistics is great, as the animal often escapes entirely or is shot. The disease can generally be diagnosed with certainty from the clinical features, but inoculation of filtered human saliva into the brain of a rabbit is usually undertaken as a confirmatory test. Treatment consists of cauterising the wound, followed by the usual inoculation of the dried cords of rabbits. Should violent symptoms arise they can often be controlled by hyoscine and morphine, while injections of novarsenobenzol are sometimes employed. Pathological investigations into the disease have been disappointing, Negri bodies being found in only 20 per cent. of undoubted cases.

Goitre.

Egypt appears to offer a very interesting field for the investigation of the ætiology of goitre. While adenomatous goitre is not uncommon, "disorders of secretion resulting, on the one hand, in hyperthyroidism or exophthalmic goitre and, on the other, in myxœdema or cretinism are almost unknown."[7] This refers more particularly to the fellaheen, for amongst Egyptians of wealth and leisure these latter diseases are found much more frequently. The conclusion has been reached that as far as adenomatous goitre is concerned it is almost entirely due to a polluted water-supply in non-riparian villages. With regard to the absence of disorders of secretion of the thyroid gland among the labouring classes of Egypt, a very interesting field for speculation is thrown open. Whether it is something to do with the diet, the rarity of nervous diseases, the free uncomplicated life which is led, or due to an inherent difference in the endocrine balance of the Egyptians remains a fascinating and open question.

Hospital Accommodation.

While there is about one hospital bed to 800 inhabitants in Cairo, the proportion reaches about 1 to 15,000 in the provinces, and the pressing need for extended hospital accommodation is evident. This need of the provinces for additional hospitals must not, however, be allowed to overshadow completely the fact that if Cairo is to maintain its position as a great centre of clinical instruction a new hospital is necessary there, and it is a matter for regret that the projected scheme for the rebuilding of the Kasr-el-Ainy Hospital in Cairo is at present at a standstill. As far as special hospitals are concerned, Egypt seems to be in a particularly happy position with regard to ophthalmic work. Thanks to generous private donations and enlightened State aid, an ophthalmic system has been built up consisting of five completely-equipped travelling hospitals, 16 permanent hospitals, and two ophthalmic departments attached to general hospitals. Through the devoted labours of a British administrator a highly efficient staff has been collected, and with the clinical aspect kept strongly in the foregound much of the administrative work has been successfully relegated to clerical subordinates.

The Future.

The future of medicine in Egypt is a matter for speculation. With a host of historical associations and the products of modern public health work under British direction, time will show whether the Egyptians will be able to cope more or less unaided with complicated hygienic conditions and maintain the comparatively high reputation which the Cairo School of Medicine at present enjoys. It possesses unrivalled opportunities, as recent papers published in our columns amply demonstrate, and it has a rich and interesting clinical field. It requires judicious development and a modern hospital with a wise and temperate control, free from political passion and racial bias. Given these it should become the medical Mecca of the Near East. On the other hand, ineffective control, political interference, or a policy of *laissez-faire* will almost certainly lead to decadence and eventual disaster.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Scottish Universities Election.

AT the time of writing great political interest is being taken in the contest for the three seats representing the four Scottish Universities, the only constituency in the country not yet decided. At first sight the process of electing the candidates seems slow, but considerable difficulty is being experienced by the Registrar through members of the General Council of each University failing to keep in touch with their University or to register change of address. For this reason a great many letters enclosing voting forms have been returned by the postal authorities. There appears to be a misunderstanding in some cases that the General Council of any University is the same body as the General Medical Council, and that the compulsory notification of change of address to the latter is sufficient. The two bodies are entirely distinct and any change of address should be sent to each Council; in this way much inconvenience and disappointment may be avoided. In ordinary circumstances little more than a passing interest is taken by graduates in reports circulated by the University Council, and their non-arrival is not missed. At elections members are naturally annoyed when voting papers do not reach them, completely losing sight of the fact that in the past some change of address has not been sent in. This is especially the case at present when the University seats have been for so long uncontested, and therefore no necessity has arisen for an election.

Aberdeen Medico-Chirurgical Society: Tumours of the Breast.

At the opening meeting for the winter session of this Society Dr. G. M. Duncan, the President, delivered his presidential address on Tumours of the Breast. Dr. Duncan's experience of such cases extended to several hundreds, and after some preliminary remarks upon the importance and difficulties of histo-pathological examination, he dealt first with the carcinomas. Points of interest in these tumours were the rarity of their occurrence in the male breast (in the series only six were in the male); the difficulties of diagnosis in the early stages; and the extraordinary high percentage of carcinoma in all breast tumours. Dr. Duncan described the method of rapid diagnosis by sections at operation, and thought that this method might be more extensively used, provided that the pathologist had the necessary experience of the technique and the appearance of such sections. Illustrative cases were quoted where the method had been of considerable value. The different varieties of breast cancer were then described, and special reference made to the difficulties of diagnosing cancer commencing in a mastitic breast, and of distinguishing malignant types of papilliferous cyst-adenoma. From his experience of cancer cases Dr. Duncan drew certain general conclusions: (1) Cancer of the breast in young women tended to be much more malignant than in those of greater age. (2) Cancer associated with inflammatory conditions of the breast often tended to be peculiarly malignant. (3) Speaking generally, he held that the more cellular the character of the growth the more malignant it was. (4) It was unwise to draw any definite conclusion merely from the size of a growth as to its malignancy both local and from the point of view of the occurrence of metastatic deposits. Cases were quoted showing that a large growth might be removed with complete success, while a small growth might be removed with rapid local recurrence or development of metastatic deposits. Emphasis was laid on the occasional occurrence of metastatic growths producing definite physical signs, where the primary tumour in the breast was so small as to require the most careful examination for its detection. Dr. Duncan then described other types of breast tumour, for example, fibro-adenoma, sarcoma (very rare), inflammatory conditions, syphilis, and tubercle. He suggested that some of the vague fibrotic conditions found in the breast might, in certain instances, be of syphilitic origin.

Edinburgh: Jubilee of the Longmore Institution.

This hospital for incurables, which is under the management of the Royal Edinburgh Hospital for Incurables, has now just celebrated its jubilee. Originally intended to accommodate 22 beds, there are now 160, while an auxiliary institution at Liberton has more than 50 beds, thereby multiplying the original number of beds by nearly ten. For this much credit is due to the management, as in the first 20 years of the existence of the hospital the total deficiency was under £2000, while the total sum drawn from capital to meet the deficiency on annual income, over £93,000, was made up from legacies and donations. Sir Henry Cook, the chairman of the board of management, who presided on Nov. 7th at the fiftieth annual meeting of the board, referred to the satisfactory progress that had been made, and expressed the hope that the voluntary effort of our great healing institutions would never be superseded by a paid management. Sir Leslie Mackenzie, a member of the Scottish

Board of Health, said that in the last full year the number under treatment in the two hospitals was 345, and that in the past 25 years more than 35,000 cases had been admitted. Sir Harold J. Stiles moved a vote of thanks to the managers. Referring to the Liberton Hospital, he said that when he saw the outside huts he realised how it was that some of the cases of tuberculous diseases of the spine which were sent into the hospital incurable had gone out cured.

Medico-Chirurgical Society of Edinburgh.

The opening meeting of this Society took place on Nov. 5th. The meeting opened with the election of new office-bearers who, together with those already in office, are:—President: Sir David Wallace. Vice-Presidents: Dr. George Mackay, Dr. Robert Thin, Dr. William Guy. Councillors: Sir Robert Philip, Dr. Chalmers Watson, Dr. John Orr, Dr. J. A. H. Duncan, Dr. A. H. H. Sinclair, Dr. W. T. Ritchie, Dr. J. S. Fraser, Mr. J. M. Graham. Treasurer: Dr. W. Macrae Taylor. Secretaries: Mr. W. J. Stewart, Dr. John Eason. Editor of Transactions: Dr. Fergus Hewart. The following new members were elected: Dr. H. R. Dodson, Dr. J. Donald Gunn, Dr. James Irvine, Dr. Alexandra Lothian, Prof. T. J. Mackie, Dr. W. N. Boog Watson, and Dr. A. R. Wightman. During the session eight ordinary meetings are arranged, commencing at 8 P.M. The dates of the remaining seven are: Dec. 3rd, Jan. 21st, Feb. 4th, March 4th, May 6th, June 3rd, July 1st. In addition there will be two clinical meetings in the Medical Out-patient Department of the Royal Infirmary on Nov. 19th and May 13th at 5 P.M.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Prosecution for Soliciting a Bribe.

AN important prosecution took place in the Central Criminal Court, Dublin, last week, when two members of the late Co. Roscommon Board of Health, recently dissolved, were found guilty of soliciting fees or rewards to induce them to vote for the election of a particular candidate as medical officer of a dispensary district in the county, as I wrote in my letter of Oct. 18th. Prosecuting in the first case, that of John Corrigan, Mr. Carrigan, K.C., said that the case was an important one, involving a charge of attempted corruption to secure the vote of a member of the Board. The prosecution was brought under the Public Bodies Corrupt Practices Act. The offence was a misdemeanour, and one consequence of conviction would be to deprive the man convicted of the right to vote for seven years. It was not necessary that any money should pass. The offence was in corruptly soliciting for himself or another a fee or reward to bring about such an election. Evidence was given by friends of Dr. T. P. McDonnell that when they asked Corrigan to vote for Dr. McDonnell he replied, that "none of the candidates was a brother of his, and he would vote for the man who paid him most." In the other case, Dr. McDonnell swore that Thomas Moran had told him he could have his vote for £50, or that for £400 or £500 he could secure enough votes to make sure of the election. In both cases, after a verdict of guilty, the prisoners were put back for sentence. For years past rumours have been current that elections by local authorities are influenced not merely by undue family and political connexions, but are subject to bribery and corruption. This is the first occasion on which anyone has been prosecuted on such a charge. Immediately after the election Dr. McDonnell objected to it on the ground of bribery and demanded a sworn inquiry by the Ministry of Local Government and Public Health. The inquiry was promptly held, and enough evidence was forthcoming to justify the criminal prosecution, which has now been brought to a successful issue. The activity of the Ministry of Local Government in investigating the charge and of the criminal authorities in ordering a prosecution is highly satisfactory. Such action will, it is hoped, teach a lesson to rogues in other parts of the country who may be prostituting the interests of the public and of the sick poor to their own profit.

Physical Training in Schools.

On the invitation of the Co. Dublin Branch of the National Athletic and Cycling Association of Ireland, a conference was held last week in the Royal College of Surgeons to discuss the steps that should be taken to introduce a system of physical training into the schools of Ireland. Mr. P. Lynch, K.C., presided, and the conference was attended by representatives of the Irish Medical Association and a number of persons interested in health and education. It was stated that there was already a fair system of physical training in the secondary schools, but none in the primary schools. The importance of physical training to improve the health and physique of the race was emphasised. It was pointed out, also, that the time was opportune to press the matter, as a system of medical inspection of school-children was about to be put in force, and the two reforms should go together. After an informative discussion a small committee was elected to study the systems in vogue in other countries, and to press its views on the Ministry of Education.

AMERICAN PUBLIC HEALTH ASSOCIATION.

FIFTY-THIRD ANNUAL MEETING.

(FROM OUR OWN CORRESPONDENT.)

MEMBERS of the American Public Health Association, drawn from all parts of the United States and from Canada, met in Detroit for their Fifty-third Annual Convention from Oct. 20th to 23rd. On the first day, when the addresses of welcome were delivered, over 600 had registered their presence. The President of the Association, Dr. W. H. Park, is recovering from an attack of pleurisy and was not able to be present. His place was taken by Dr. J. W. S. McCullough, of Toronto. After welcoming addresses had been given by the Mayor and Health Commissioner of Detroit, Dr. Thorvald Madsen, Chairman of the Health Section of the League of Nations, described the work of that body. Many members of the large audience were not able to hear Dr. Madsen, who speaks with more of an English than an American accent, and on this account, coupled with the political distrust of the League which is still found amongst Americans, the very careful and wise analysis of the work of the Health Section did not excite the interest which it deserved. Dr. Victor C. Vaughan followed with a lively impromptu address largely in praise of Michigan. He told the audience, among other historic achievements of his fellow citizens, that a member of the health department had discovered in the 'eighties a method of artificial respiration which had been widely taught and practised as the Michigan method. When Sir E. S. Schafer came to Detroit and described his prone pressure method it was found that the two were practically identical. Dr. Vaughan maintains that we should not be satisfied with raising the expectation of life while neglecting the quality of the lives we prolong. It does not profit us to increase the number of youthful degenerates and senile dements. Dr. Vaughan proposes to devote the rest of his life to the improvement of the human stock. These speeches were followed by an informal reception and dancing. The main work of the conference was divided between the various sections which sat more or less contemporaneously—an indication that even the field of public health in this country is not kept free from the vice of specialisation.

PUBLIC HEALTH ADMINISTRATION.

In the Public Health Administration section the Dick tests and immunity results in scarlet fever came under review. Among other subjects discussed, Dr. Adam H. Wright, of the Toronto Department of Health, considered the cause or causes of cancer. He was not hopeful that a specific cause of cancer would be discovered nor that we should be greatly helped by its discovery. The discovery of the tubercle bacillus had not helped greatly in the treatment of consumption.

An impressive study was that reported by Dr. Haven Emerson on

Hospital Morbidity Statistics.

Five years' experience with scarlet fever, diphtheria, and measles covering 16,435 hospital admissions had been analysed to determine if possible a basis for judging of the value of hospital care for these diseases, and to formulate principles of hospital practice which would contribute to (*a*) a lower mortality from the original or primary infection; (*b*) a reduction in the incidence of secondary infections; (*c*) fewer complicating lesions; (*d*) a shorter period of hospital care. It appeared to be true that periods of crowding and shortage in nursing personnel were always accompanied by higher case mortality-rates, together with higher incidence of secondary and complicating infections, this experience suggesting the propriety of establishing minimum floor space per patient and maximum patient ratio per nurse expressed in hours of nurse service per patient per day or week. The death-rate among children under 2 was so high, especially in measles, that it was believed inadvisable to admit such patients to hospital care even when the home conditions were unfavourable, if by visiting nurse service passable conditions could be provided. He said that the frequency with which deaths occurred within the first 48 hours after admission, especially from diphtheria and from pneumonia in measles, indicated the necessity of renewing the education of physicians in the early and adequate use of diphtheria antitoxin in suspicious cases and of declining to permit transfers from other institutions in cases of measles where complicating pneumonia had already set in.

Dr. R. G. Leland, Chief, Division of Hygiene, Ohio Department of Health, Columbus, Ohio, laid down certain essentials in the

Administration of a Public Health Nursing Service.

Public health nursing had, he said, come to occupy a foremost position in combating preventable causes of disease and death. It had shown a marvellous growth both in volume of work and breadth of application; it should be almost entirely educational in character. He held that whatever the community problem and number and type of local groups interested in public health, the nursing service should be directed by the administrator of the official health agency. Compensation for health nursing should be consistent with the type and dignity of the service. The value of a service that prevents sickness and prolongs life is too often unfairly estimated.

The question of generalised versus specialised nursing was taken up again at a public health forum, and gave rise to a lively discussion. Dr. Haven Emerson and Miss Elizabeth Fox declared for generalisation under supervision of specialists, the former laying down the standard of one nurse for every 2000 population as a minimum.

SECTION OF LABORATORIES.

In the Laboratory Section the influence of intensive work on diphtheria carriers upon the diphtheria morbidity was discussed by Dr. W. Royal Stokes, Dr. John F. Hogan, and Mr. C. Leroy Ewing, of the Bureaux of Bacteriology and Communicable Diseases of the Baltimore Health Department.

After reviewing the literature to show the relative prevalence of diphtheria carriers and positive virulence tests in convalescents, non-contacts in the general population, and contacts with cases of diphtheria, the speakers stated that practically all cultures from convalescents were virulent, whereas in a general mixed population, excluding schools and other institutions, 0·09 per cent. show virulent diphtheria cultures. The speakers referred to their study of a large number of initial contacts in Baltimore where they found that about 1 in every 100 harboured virulent diphtheria bacilli as against about 1 in 1000 in the general community. The statistical evidence presented was not very conclusive. They then described the methods pursued in Baltimore and 17 other comparable cities in detecting and isolating initial contact carriers, and in finding additional release carriers when the house was reported for the release of quarantine.

INDUSTRIAL HYGIENE.

The meetings of the Section of Industrial Hygiene were not well attended, and although those who were present showed a lively interest in the proceedings there was evident a sense of dissatisfaction with the present control of occupational disease.

Prof. H. Field Smyth spoke of anthrax as a "continuing and probably increasing hazard" of American industry. Although satisfactory methods were available for the disinfection of hair and wool they were not being carried out properly in the smaller plants where the necessary expert supervision was not available. Speakers representing private organisations or workers' unions gave interesting accounts of their work. It was particularly gratifying to hear of a New York Union that had actually declared a strike to enforce the decisions of its sanitary board. But this represented an unusual development of the health conscience. On the whole, much remains to be done in the way of educating both employers and workers. As regards the former it must be realised that the appeal to self interest has a limit. There comes a point at which the expense of improving sanitary conditions, wages, &c., is greater than the return from increased efficiency. It would be unfortunate to set the limits of industrial hygiene at this point.

Most apparent, and in marked contrast with English conditions, is the need for better Governmental supervision of occupational diseases. Prof. E. Hayhurst, of Ohio State University, laid this need very eloquently before an open session of the convention.

REPORTS.

Some of the committee reports were inconclusive, the reporters evidently fearing that they might make a painstaking survey without its leading to any direct results.

The Committee on Nomenclature had a number of useful definitions to suggest, among them the following:—

Health in the absolute sense.—That quality of life in which the body is sound, the various organs function naturally, and the whole organism responds adequately to its environment (the definition in a relative sense is similar). *Hygiene* is the science and art of the protection and promotion of health.

The Committee on Social Hygiene reports no proof of the rumoured decrease in venereal disease. They find the attitude of the public improved and recommend attempts to control procuration and to enforce quarantine of diseased individuals. The Committee on Cancer suggests that health officers attempt to secure the reporting of cancer morbidity. Free pathological examinations should be available. The periodic health examination is warmly endorsed.

Dr. Henry Vaughan was elected President of the Association for the coming year, and it was decided to hold the 1925 convention at St. Louis.

DONATIONS AND BEQUESTS.—Miss Rosalie Anne Le Geyt, Jersey, left £1050 to the Royal Hospital for Incurables, Putney, and £1000 to the Royal United Kingdom Beneficent Institution.—Miss Clara Walker, of Bideford, Devon, left £1000 to the Bideford and District Hospital.—Mr. Thomas Henry McCormick, of Lancaster, left £500 to Ancoats Hospital, Manchester.

"Audi alteram partem."

TREATMENT OF MENTAL DISORDER ON A VOLUNTARY BASIS.

To the Editor of THE LANCET.

SIR,—I have read with great interest Dr. Edward Mapother's views on this subject in your issue of Nov. 1st, and I admit, as everyone must do, his high qualifications to maintain the opinions he has expressed. I believe, however, that Dr. Mapother does not entirely do justice to the facilities available in existing mental hospitals, and I ask permission to set forth some of the experiences gained in the treatment of mental diseases on a voluntary basis in an old-fashioned asylum, working under that name.

I should say that this Asylum, which contains 150 beds, cares only for patients of the private class, but many are admitted at low rates of board, and are not distinguishable socially from the rate-aided patients in a county asylum. During the last four years (ending Sept. 30th) 231 patients have been admitted, of whom 111 were certified and 120 (or 51·9 per cent.) entered as voluntary boarders. (No selection of cases has been carried out, and every patient who offered was accepted.) The voluntary admissions represent 103 individuals, of whom one entered six times and 12 entered twice. In addition, seven patients previously certified entered voluntarily and are included in the total voluntary admissions.

The criteria for admission on a voluntary basis are: (1) a recognition on the part of the patient that he is ill (without necessarily any insight or appreciation of the nature and origin of his illness), and (2) willingness to allow himself to be treated, as expressed in a signed application for admission. I am aware that pressure is put upon hesitating and doubtful applicants for admission by their friends and relatives, the threat of certification and compulsory entry being the usual instrument. I am no party to any such pressure. If I see a dubious patient before he has made up his mind, I limit myself to the statements that whether he enters or not is a matter of complete indifference to me, that if he decides to do so I shall do what I can to recover his health and make him comfortable, that if he does not like the place he can go away whenever he likes; lastly, that *under no pretext* will he be detained against his will.

During the same period 112 voluntary patients left the Asylum as follows: recovered, 49; relieved, 42; unimproved, 7; died, 14. The average length of stay of the recovered was $4\frac{3}{5}$ months, and of the relieved $13\frac{2}{3}$ months.

The retention of voluntary patients in an asylum for as long as may be necessary for their safety or advisable for their treatment presents much less difficulty than is generally supposed. No distinctions whatever between voluntary and certified patients are made in treatment and accommodation, and many of the certified are unaware of their inferior status. Classification according to the mental state alone is aimed at, but not at all times perfectly achieved. The building is old and in many respects badly designed, and the different rates of board and the varying degrees of social presentability of the patients add considerably to the difficulties. In a more modern asylum and in other circumstances these considerations would not weigh. Keeping in mind the ever-present dread of depressed patients that they are becoming "insane," and their morbid sensitiveness on this subject, I agree with Dr. Mapother that asylum patients are at least as tolerant of the idiosyncrasies of their fellows and of the phenomena around them as are the patients in an ordinary medical ward, and in my experience the complaints of asylum patients are seldom directed against the behaviour of their neighbours.

During the four years three voluntary patients, to whom I had made no promises, were certified and detained in the Asylum. Two of these (1921) were cases of acute mania, whom I should not now willingly receive as voluntaries (both recovered quickly), and the third (1922) was a mild case of chronic mania who made no effort to leave, but who, in spite of repeated warnings, caused alarm among some of the new patients by asserting that he was illegally imprisoned. (One voluntary was certified in order to be removed to a county asylum.) No patient previously voluntary was received under certificates. Twelve patients persisted in leaving against advice. Of these, eight returned after a short interval and continued treatment, and the other four eventually did well at home. Six of the unimproved patients were removed by their relations for various reasons. One voluntary patient committed suicide during an interval of relaxed observation, and another removed by his friends for financial reasons killed himself the day after his discharge.

Rarely a new patient is admitted directly into a convalescent villa or ward, but, as a rule, all patients enter the hospital wards. From that they are duly passed into one of the four other wards or villas available for each sex, or occasionally for special reasons, if the stay is likely to be short, kept in the hospital ward till discharge. Parole is granted to both classes of patients as a matter of course as soon as justifiable, and one aims at the least possible degree of interference and restriction of liberty. Three of the female and two of the male wards are kept locked, but a number of patients from every ward in the Asylum, including hospitals, enjoy parole. Three of the male wards are in charge of nurses.

In conclusion, I agree with Dr. Mapother that the Maudsley Hospital as at present administered offers an ideal method of dealing with a section of the mentally unfit, and with his opinion that in our time the provision of such hospitals in sufficient numbers is impracticable. I differ from his view that voluntary patients cannot adequately be treated alongside the certified, and I have tried to indicate the evidence on which my conclusion is based. The displacement of "The Asylum," either the institution or the name, is not at present practical politics, and the aim should be to render it as fit an instrument for its varied purposes as may be. Mental patients will not voluntarily enter or remain in any institution in which they have not complete confidence, and the demonstrable fact that such patients are entering and returning to existing asylums in appreciable numbers indicates a change in the attitude of the public which should be fostered and encouraged. The more voluntary patients to pass through an asylum the sooner will any weak points in its methods be eliminated. Pessimistic views expressed by medical men on asylums and their value as hospitals are to be deprecated, because no one can estimate how much good work asylums, unhampered by antiquated laws, may be capable of. Unless and until medical knowledge advances to a point where prognosis becomes a certainty, attempts to separate mental sufferers into "sheep" and "goats" will be cruel and dangerous, and thinly veiled attempts to degrade asylums to the mediæval level of a "house of doom" exclusively populated (and presumably also staffed) by hopeless dements, should be strongly resisted by all those who really know anything about them.—I am, Sir, yours faithfully,

W. D. CHAMBERS, M.D., M.R.C.P.E.,
Physician-Superintendent.

James Murray's Royal Asylum, Perth,
Nov. 8th, 1924.

DENTAL DRESSERS.

To the Editor of THE LANCET.

SIR,—I only trouble you with a reply to the letter of Dr. Kerr in your issue of Nov. 8th because he is still grievously in error as to his facts. May I therefore explain to him that the name "dental hygienist" is given to a class of unregistered persons, employed under certain clearly defined limitations, in dental hospitals and public dental clinics in America, in cleaning and polishing the teeth of school-children and in removing superficial deposits of salivary calculus. If Dr. Kerr will read Circular 1279 issued by the Board of Education, he will find that the Minister of Health, after consultation with the Dental Board, has sanctioned "minor dental work" of this nature and that any local educational authority is at liberty to make use of it in school dental clinics.

Dentists, knowing something of the delicacy of the tissues involved and the possibility of injury to the periodontal membrane through the weakening or destruction of the natural defences in the "gingival trough," do not look with favour on the widespread application of these methods. They believe they have pointed out to the authorities a more excellent way. The work done by these dental hygienists has no resemblance to that done by "dental dressers" under the scheme of Dr. Barwise, and I readily accede to Dr. Kerr's request for a statement of the reasons why the dental profession is opposed to the employment of dental dressers.

It is claimed that these persons shall be allowed (1) to conduct dental inspections of the mouths of elementary school-children away from the supervision of the dentist with probe and mirror; (2) to extract temporary teeth; (3) to insert simple fillings; and (4) to treat the first permanent molar. My reply to these claims is this:—

1. The school nurse can by a glance into the mouth of a child and by one or two simple questions, ascertain whether there is need for the child to go to the school dentist. "Inspection with probe and mirror" is a very different thing. It implies diagnosis: otherwise it is a waste of time, as the dentist must re-inspect each case before he can decide on the treatment necessary. Surely the claim that no professional man could consent to accept and to work on the diagnosis of an unqualified subordinate will receive sympathy from the members of the medical profession.

2. Extraction of temporary teeth is not necessarily a simple operation. On the contrary, it is frequently a difficult and delicate operation which, if improperly performed, may result in danger to the permanent dentition.

3. The remarks about extractions apply also to "simple" fillings. It is the constant experience of skilled dentists that cavities which appear "simple" develop during treatment into difficult and complicated cases; a partially-trained person would, of course, not appreciate this.

4. The treatment of the first permanent molar. This tooth is regarded by all competent authorities as the most important tooth in the dental arch. Upon its proper treatment the future masticating efficiency of the child may depend, and none but qualified dental surgeons should be allowed to deal with it.

The dental treatment of children is one of the most delicate and difficult departments of dental surgery, and demands high qualities of skill and dexterity. It is difficult to understand why elementary school-children should be abandoned (on the specious plea of economy) to a course of treatment which, were it attempted in the case of any other children in this country, would render the operator liable to prosecution and the dentist who sanctioned the treatment to the discipline of the Dental Board for "infamous conduct in a professional respect." The sacrifice made by the dental profession to obtain prohibition of unregistered practice of dentistry is surely not yet forgotten. That sacrifice was made on the understanding that it was final, and that not again would the conditions that existed prior to the passing of the 1921 Act recur. The creation of large numbers of unregistered persons permitted by law to perform certain operations in dental surgery would almost certainly result in a future claim for their admission to the Dentists Register. That this is no vain fear is shown by the fact that when the short amending Act of 1923, which gave certain privileges with regard to the age-limit to ex-Service men, was in committee in the House of Commons an amendment was brought forward with the object of giving dental dressers access to the prescribed examination and therefore to the register.

These, briefly stated, are the objections taken by the dental profession to the employment in the school dental service of dental dressers as advocated by Dr. Barwise and supported by Dr. Kerr. With the memory of their own escape from the evil of unqualified assistants, is it too much to ask our colleagues of the medical profession to refrain from assisting the imposition on the dental profession of a like evil, one from which they so lately escaped at a great price?—I am, Sir, yours faithfully,

ROBERT LINDSAY,
Dental Secretary.

British Dental Association, Russell-square, W.C.,
Nov. 8th, 1924.

To the Editor of THE LANCET.

SIR,—If sound conclusions are to be reached, discussion must be based upon facts. To ignore these, or to dismiss them as trivialities, is not conducive to that spirit of scientific inquiry which should precede such reforms as may be desirable in the school dental service. It has already been pointed out in your columns by Mr. Pitts and Mr. Lindsay that there is no shortage of dentists at the present day. In so far, therefore, as the case for the Derbyshire Education Authority is based upon an alleged shortage, it has no foundation in fact. To Dr. Kerr this is a triviality.

The school dental service, at present in an elementary stage of its evolution, lacks many things. One of the most pressing wants is the need for skilled nursing assistance. It should be part of the nurse's duty to give instruction in oral hygiene, to inspect the teeth of the children, and to carry out surface cleaning where possible. In Poor-law schools, where practical instruction such as this is given, the result has been that a considerable proportion of Poor-law children have healthy mouths. The percentage is far higher than the percentage in elementary school-children. Similar results have followed the work of the dental hygienists in the United States. Their work consists in surface cleaning; they are not operating assistants and should not be confused with such.

The agitation of the protagonists of the Derbyshire scheme brings the members of the dental profession face to face with a question of principle. This question is: Is it right that dental operations should be performed by unregistered persons? Recent legislation has answered this question in the negative.

I am, Sir, yours faithfully,
H. W. BREESE, M.R.C.S., L.D.S.

Nov. 11th, 1924.

PUBLIC BATHS: A SUGGESTION.

To the Editor of THE LANCET.

SIR,—At the present state of the problem of housing the general community, particularly that section to which the Chamberlain Act applies, it may be questioned whether the space allotted to the bathroom in small houses really fulfils the object for which it was intended. Cleanliness is a postulate of health, but whether a house contains a bath or not is no criterion of the state of cleanliness of the occupants; the first essential is the possession of enough money to provide hot water, and the second is the acquired habit of preferring to be clean rather than dirty. In fact, to make sure that a family is clean there must be (i.) a bath, (ii.) hot water, towels, and soap, and (iii.) the will and desire to make use of them. Everybody who has any experience of the way the poorer classes are housed and their mode of life, knows that vast numbers of baths are used as coal stores, rubbish shutes, cots, &c., in fact, for anything but the purpose for which they were installed. In nearly every case where this is so, the reason for it is the financial one. An appreciable quantity of coal is required to heat eight or nine gallons of water. The anomalous state now exists that new small houses are being erected containing baths and bathrooms which cannot be used owing to the expense, and the removal of the bath would very materially improve the accommodation.

My suggestion is that we should not build bathrooms in small private houses, but enlarge the existing public baths, and encourage public bathing. The only trouble in this case is that people would not use the public baths because it is not the custom in this country, as it is in parts of the continent. Every individual is sensitive about personal cleanliness, and there is a prejudice against many such public institutions.

Obviously the habits of the older generation cannot be changed; but those of the younger can. If, for the school child, a hot bath, free, once a week and in school hours, were made a part of the school curriculum, and insisted upon by the Board of Education, then a habit of bathing would be engendered which would last long after school-days are over. In two or three generations public baths would be as fashionable and customary as they were in Rome two thousand years ago.

Of course, the financial problem, if this suggestion were carried out, would be an intricate one. Actually it must be cheaper to provide public baths which will be used, than to instal a bath in each of the two and a half million houses required, enormous numbers of which will never be used. Even if it turned out to be a financial loss to the State in actual hard cash, the Board of Education might pay 1*d.* per bath for the school-children, and the individual above school-age would pay for himself; and the local authority need not be the loser. A clean-bodied nation with all the improvements in environment which would spontaneously follow, would be a gain to the nation in the greater man-power which would become available, and this would more than off-set the financial loss. The present sick wastage due to minor ailments of the impetigo type is enormous and these might conceivably be abolished altogether.

I am, Sir, yours faithfully,

Southampton, Nov. 8th, 1924. A. G. G. Thompson.

GENERAL MEDICAL COUNCIL ELECTION.

To the Editor of The Lancet.

Sir,—Will you allow me, through your columns, to thank the Registered Medical Practitioners of Scotland for the expression of their confidence shown by my unopposed return to the General Medical Council as their Direct Representative. It shall be my constant endeavour to continue to merit their trust.

I am, Sir, yours faithfully,

Edinburgh, Nov. 8th, 1924. Norman Walker.

HYPERTONIC SALINES IN CEREBRAL TUMOURS.

To the Editor of The Lancet.

Sir,—I have read with considerable interest the work of Drs. Macbride and Carmichael on the use of hypertonic salines in cerebral tumour.

A false impression might be conveyed by their statement that "we are unable to confirm Cohen's experience as to the duration of the relief. In all our cases the alleviation of the headache did not last more than 36 hours, hence we have repeated the administration of the solution every second day." In my paper I wrote "this period of freedom lasted from 10 hours to two days, but in most cases an intravenous injection every third day kept the patient free from headache."[1] By every "third" day I mean a 48-hour interval between the injections, which, I think, is what Drs. Macbride and Carmichael mean by every "second" day. Whenever necessary I have repeated injections as often as 20-hourly without apparent untoward result. Further extensive experience of the method has confirmed its value.

I am, Sir, yours faithfully,

Henry Cohen, M.D. Liverp.

University of Liverpool, Department of
Biochemistry, Nov. 11th, 1924.

---

[1] Brit. Med. Jour., March 8th, 1924.

GENERAL MEDICAL COUNCIL: ELECTION OF DIRECT REPRESENTATIVES.

England and Wales.

An election address has been issued by Dr. H. J. Cardale, Dr. H. F. Devis, Dr. E. A. Gregg, and Dr. G. R. Ward, from the office of the Medical Practitioners' Union (56, Russell-square, London, W.C. 1), to the registered medical practitioners of England and Wales, which runs as follows:—

A Four-Point Programme.

Dear Sir (or Madam),—We, the undersigned, have been nominated as candidates for election as direct representatives for England and Wales on the General Medical Council. W are all in active general and panel practice, and experienced in public work.

The General Medical Council was set up so long ago as 1858, and deals with professional education and discipline The last eleven years have brought the general practitioner so closely into relationship with State Departments, and have seen so great an increase of public interest in things medical, that neither the old education nor the old conception of discipline are any longer adequate.

Moreover, only six out of the total membership of the General Medical Council are directly elected by the profession On the present Council only three practitioners out of forty one are in general practice. There is a growing necessity for increased representation of the general practitioner more especially as the disciplinary powers of the Genera Medical Council which are exercised in his case are almost entirely in the hands of men who know little or nothing o his life under modern conditions, his vexations, his trials and the curtailment of his freedom.

We feel that the scope of education at the present time is almost entirely dictated by those who have no experience of general practice, with the result that it is, in many directions, unsuited for the requirements of general practitioners who form the vast bulk of the profession. The weak points in the education of the future doctor can be most adequately appreciated and their effect most fully realised by those who are themselves engaged in general practice.

We are in favour of a uniform examination for entry to the profession instead of the present varying standards

As general practitioners of considerable experience anxious to safeguard your interests, and alarmed at th encroachment on your freedom, we ask your support in favour of:

(*a*) Increase of direct representatives;

(*b*) Modification of the scope of medical education to sui the requirements of the general practitioner;

(*c*) Uniform standard of examination;

(*d*) A wider range of disciplinary powers.

H. J. Cardale,
Vice-President, Medical Practitioners' Union Chairman, London Panel Committee; Member Insurance Acts Committee, British Medica Association; Member, London Insurance Committee, &c.

H. F. Devis,
Past-President, Medical Practitioners' Union Secretary, Bristol Panel Committee; Member Bristol Insurance Committee, &c.

E. A. Gregg,
President, Medical Practitioners' Union; Membe Insurance Acts Committee, British Medica Association; Vice-Chairman, London Pane Committee; Chairman, Public Health Committee, St. Pancras Borough Council, &c.

Gordon Ward,
Chairman, Executive Committee, Medical Practitioners' Union; Member and Representativ Kent Panel Committee; Member, Ken Voluntary Hospitals Committee, &c.

Dr. John Brown's election address unfortunatel reached us too late to be quoted in full. After settin out his reasons for standing for election, to which w gave publicity last week, Dr. Brown makes the following suggestions for the reconstitution of the Genera Medical Council:—

"The Medical Council Act of 1858 and the Medical Act o 1886 are hopelessly out of touch with the ideals of to-day The Medical Council is far too large and too costly. suggest very briefly the following: The number for th present should be reduced to 36, in fact 30 might be eve more effective. There should be 18 to be elected from th licensing bodies and 18 for England and Wales, Scotland and Ireland. England and Wales to have 12, Scotland

and Ireland 3. This would be fair in regard to population as a basis for proportional representation. In regard to the Direct Representatives the 18 should be equalised on the basis of population. Definite areas must be made so that there shall be opportunity for candidates to visit the electors."

In Dr. Brown's opinion the National Insurance Act must be very greatly altered, so that the Ideal Family Doctor be restored. The Medical Curriculum must be changed so that the Prevention of Disease shall be the "key-note," and the cure second. The 27 Universities' Colleges ought to be federated so that there shall be uniform standards of examination and of fitness for the profession. Dr. Brown heartily supports Sir George Newman's Memorandum on recent advances in medical education in England.

Obituary.

ALFRED JASPER ANDERSON, M.B. OXF., M.R.C.S. ENG., D.P.H. CAMB.,

MEDICAL OFFICER OF HEALTH FOR CAPE TOWN.

THE death is announced of Dr. A. J. Anderson, medical officer of health of Cape Town, a well-known South African medical man whose labours on behalf of a Public Health Act and the establishment of a Ministry of Health in South Africa, now an accomplished fact, no less than in the cause of child-life protection have been of wide service. Born at Manchester in 1858, he was educated at the Manchester Grammar School. At the University of Oxford he graduated M.B. in 1883, having in the previous year taken the M.R.C.S. Eng. A student at St. Bartholomew's Hospital, he afterwards visited the medical clinics of Leipzig and Vienna, and in 1888 obtained the D.P.H. Cambridge. From 1891 to 1901 he was medical officer of health for Blackpool; he then went to Cape Town to fill a similar office. He gave himself whole-heartedly to public health work, advocating as a foundation on which to build reforms, a department of public health for the Union, the passing of a Public Health Bill to codify existing Acts and Ordinances, the compulsory appointment of women health visitors, the establishment of large municipal infant welfare centres, and the teaching of domestic science and mothercraft to girls in schools. Although much still remains to be done, Dr. Anderson has been able to see vast improvements in the directions in which his foresight visualised the need. But Dr. Anderson's vision was not confined to the particular part of the Empire in which he exercised his calling, nor to any circumscribed division of public health and hygiene. In 1922, while in England, he contributed to the Section of Tropical Diseases of the Royal Society of Medicine a paper on dysentery in the British West Indies, in which he emphasised the need for encouragement and intelligent support by the Imperial Government, the importance of closer association between the insular medical services and the schools of tropical medicine in England, and for an extension of facilities to educate the rising colonial generation in preventive medicine. He specialised in the ætiology and treatment of tuberculosis, and was lecturer in hygiene in the South African College and a Fellow of the Royal Society of South Africa.

HENRY CARTER MACTIER, M.B., CH.B., B.A.O. DUB.

Dr. H. C. Mactier, hon. surgeon to the Wolverhampton Eye Infirmary, died recently at the early age of 52, after a medical record extending over 30 years in Wolverhampton, first as a general practitioner and later as an oculist. Five years ago he had a serious illness, undoubtedly precipitated by the excessive work he performed during the war and after the Armistice, and from this illness he never completely recovered. Dr. Mactier was educated at Trinity College, Dublin, where he graduated in medicine in 1894, and the following year was appointed house surgeon in the Wolverhampton and Midland Counties Eye Infirmary. In 1900 he was appointed honorary surgeon to the Wolverhampton and District Hospital for Women, and three years later became assistant surgeon to the Wolverhampton Eye Infirmary, with which he was connected, as honorary surgeon, at the time of his death. Among his other appointments Dr. Mactier acted as honorary ophthalmic surgeon to the Royal Orphanage, Wolverhampton, ophthalmic surgeon to the Bilston Education Committee, honorary surgeon to the Church Mission to the Deaf and Dumb in Staffordshire, and medical referee to various insurance societies. For his services in connexion with the war he was awarded the M.B.E. in 1920. For 27 years he was an active member of the British Medical Association, on the Council of which he served for eight years. Of his unsparing work in the interests of the profession as a whole, a colleague writes: "It came naturally to him to work rather for the common good and to sink his personal ambition in spending himself for the benefit of the profession. One wonders whether men of such ability and capacity in medico-legal work ought not to be withdrawn from the toils of practice and set apart as forensic specialists with adequate remuneration from the body medical." He wrote many papers on ophthalmological matters which were published in the medical journals. Dr. Mactier was one of the founders of the Wolverhampton Rugby Football Club and was himself a keen player. He was also an all-round cricketer and an original member of the local Tennis Club. He is survived by his widow, a son, and a daughter, to whom we extend our sympathies.

The Services.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Sub.-Lts. to be Surg. Sub.-Lts.: R. Wear and R. Russell.

ROYAL ARMY MEDICAL CORPS.

Capt. L. R. Shore, half-pay list, late R.A.M.C., is ret. on account of ill-health caused by wounds.

Capt. J. H. C. Walker relinquishes the temp. rank of Maj. on ceasing to be empld. as a Dep. Asst. Dir. of Pathology.

TERRITORIAL FORCE.

Lt.-Col. G. L. Thornton to be Brevet Col.

Majs. A. L. Otway and C. M. Ingoldby are seconded for service under the Colonial Office.

Capt. R. W. Willcocks (late R.A.M.C.) to be Capt.

Lt. C. D. Walker to be Capt.

Lt. K. J. Franklin to be Lt.

ROYAL AIR FORCE.

G. J. Hanly is granted a short service commission as Flying Officer.

INDIAN MEDICAL SERVICE.

Col. H. J. K. Bamfield to be Maj.-Genl.

Ajab Singh Garewal, E. T. N. Trevor, and A. V. Lopes are permitted to retain the temp. rank of Capt., on admission to the Ind. Med. Service in the permanent rank of Lt.

Shankar Ramchandra Joglekar to be tempy. Lt.

DEATHS IN THE SERVICES.

Col. William Lewis Gray, C.M.G., A.M.S., who died at his residence, North Holt, Hythe, Kent, on Nov. 3rd, was the son of Dr. Alexander Gray, of Selby, and was born in 1864. Educated at the Universities of Glasgow and Edinburgh, he graduated in medicine and surgery at the former University in 1885, and proceeded to the B.Sc. in Public Health at Edinburgh three years later. He joined the medical department of the Army as surgeon in 1887, and was promoted to Major in 1889, when he served with the Anglo-Siamese Boundary Commission (1889–90). In 1895 he took part in the Chitral operations and received the medal and clasp, and from 1899 to 1901 he served in the South African campaign, when he was mentioned in despatches and was awarded the Queen's medal and four clasps. In 1911 he reached the rank of lieutenant-colonel. Col. Gray, who had been commanding officer of the Royal Herbert Hospital, Woolwich, and Examiner in Chemistry at the University of Malta, took part in the late war from the commencement till 1917, in which year he received the C.M.G. He was also mentioned in despatches. He leaves a widow to mourn her loss.

Medical News.

UNIVERSITY OF OXFORD.—At a recent Congregation the degree of B.M., B.Ch. was conferred on John Wenham Alden, Non-Coll.—The University has granted, by a Decree of Congregation, a sum of £3000 towards the expense of providing a joint lecture-room, library, and workshop for the departments of physiology and biochemistry.—Sydney G. F. Plant, B.Sc., M.A., D.Phil., Magdalen College, has been appointed to a University Lectureship in organic chemistry for two years, from Oct. 10th, 1924.

UNIVERSITY OF LONDON.—The Maudsley Hospital, Denmark Hill, S.E., treats nearly 1000 out-patients and nearly 400 voluntary in-patients per annum. The cases illustrate all types of neurosis and psychosis, though particularly recoverable forms and those in which mental symptoms are associated with organic disease in the nervous system or elsewhere. In addition the Maudsley Hospital can draw upon the mental hospitals of the County of London (containing nearly 20,000 cases) and therefore affords very special facilities for clinical study. The following opportunities for this are open to medical practitioners and students without charge: (*a*) A weekly discussion at 11.30 A.M. each Tuesday of cases in the hospital. (*b*) A monthly meeting at 4 P.M. on the last Friday in each month of the medical staff of the various mental hospitals of the County of London. At each meeting a group of cases from one hospital will be shown by its staff for discussion. (*c*) Attendance at the out-patient department at 2 P.M., on Mondays and Thursdays for male patients, Tuesdays and Fridays for female patients. Appointments as voluntary clinical assistants are open without fee to practitioners of both sexes specialising in psychological medicine. Such appointments can be either whole or part time, and to work in wards, out-patient department, or laboratories as desired. They may be held in conjunction with attendance at either part of the course for the Diploma in Psychological Medicine or apart from this. The appointment will satisfy the requirements of the examining bodies in respect of clinical experience of mental disorders, for the D.P.M., or for the M.D. in Psychological Medicine.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Final Examination held from Oct. 7th to Nov. 3rd the following candidates were approved in the undermentioned subjects, but are not eligible for diplomas:—

Medicine.—J. S. Aldridge, St. Bart.'s; M. M. Baird, Oxford and Guy's; Margaret A. Bannerman, Royal Free; W. D. Beck, Birmingham; Edith D. Bowie, King's Coll.; R. J. Brocklehurst, Oxford and St. Bart.'s; Margaret H. Brown, Charing Cross; Olive B. Buckley, King's Coll.; Margaret A. L. Buckner, Univ. Coll.; Margaret E. M. Carter, St. Mary's; A. F. Chalkley, Leeds; Irene E. Chandler, King's Coll.; G. Cheney, Harvard; Gladys M. Clarke, St. Mary's; H. A. Clegg, St. Bart.'s; H. A. Cole, Liverpool; L. N. R. Comty, London; Jean Cooper, Royal Free; J. Crowther, Manchester; J. Currie, St. Bart.'s; M. Cutner, St. Mary's; R. R. Dalling, Liverpool; J. T. Daly, Birmingham; J. R. A. Davies, St. Bart.'s; W. H. Davies, Westminster; Yolande M. de la Pasture, Bristol; T. A. J. M. Dodd, St. Bart.'s; D. C. Drake, Guy's; W. Egan, Charing Cross; Norah A. M. Empson, King's Coll.; Brenda H. English, Royal Free; G. R. Ford, Guy's; Gladys Goument, St. Mary's; G. Hamada, Birmingham; J. B. Hayes, Charing Cross; Marjorie F. M. Hayward, London; L. F. Henry, Liverpool; Freda K. Herbert, King's Coll.; J. R. B. Hern, Guy's; Minnie E. Hope, Royal Free; A. O. Jacob, Madras; C. James, Middlesex; Isabel E. S. James, King's Coll.; Kate D. James, St. Mary's; E. Jones, Guy's; B. Kornblum, Guy's; W. R. Kusel, St. Thomas's; C. K. Lakshmanan, St. Bart.'s; C. N. Latham, Birmingham; Helena M. J. McQuaid, St. Mary's; R. G. Maliphant and C. Marian, Univ. Coll.; A. Mead, St. Thomas's; M. L. Millard, Birmingham; Eileen S. Morris, Univ. Coll.; G. J. Morris, V. M. Morris, and A. M. Murray, Middlesex; G. W. Murray, Guy's; E. L. Newell, St. Thomas's; R. A. Newsom, King's Coll.; R. A. Norman and J. N. D. O'Rafferty, Guy's; Madeline P. Parker, Royal Free and St. Mary's; G. H. Pringle, Univ. Coll.; L. W. Proger, Middlesex; J. E. Readman, London; J. J. R. Robinson, St. Thomas's; H. Rogers, Bristol; Alysoun H. Rowntree, Royal Free; C. E. Sharp, McGill and Univ. Coll.; D. G. Shields, St. Bart.'s; Ruby O. Stern, Charing Cross; D. D. S. Stewart, King's Coll.; A. F. Taylor, St. Bart.'s; L. D. J. Telesphor, Univ. Coll.; Josephine I. Terry, St. Mary's; T. G. Tresidder, Guy's; E. A. Trim, St. Thomas's; Mary E. Tyars, Univ. Coll.; Joan W. Urwick, Charing Cross; Elizabeth M. Weideman, St. Mary's; D. G. Williams, King's Coll.; Emily A. C. Wilson, Charing Cross; N. Wilson, Univ. Coll.; and R. H. Yelf, King's Coll.

Surgery.—J. D. Allen, St. Bart.'s; D. Aserman, St. Thomas's; M. Bannounah, Guy's; T. F. Barlow, London; C. E. G. Beveridge, St. Bart.'s; V. H. Boobbyer and E. H. Boodrie, St. Mary's; D. De C. Boxill, Long Island Hosp. and St. Mary's; R. N. Brandwood, Guy's; M. K. Braybrooke, St. George's; D. J. Brims, St. Bart.'s; Stella M. Brown, King's Coll.; W. A. Browne, St. Mary's; the Hon. C. B. Buckley, St. Thomas's; H. H. Bullough, Manchester; W. H. Cameron, Middlesex; A. F. Chalkley, Leeds; J. H. T. Challis, London; G. Chambers, Leeds; Eileen A. Chennell, St. Mary's; W. E. Cheesman, St. Thomas's; J. E. Church, St. Bart.'s; L. C. Cook, St. Thomas's; A. S. Cox, Bristol; D. P. Crawford, St. Thomas's; Dorothy E. Crellin, Bristol; A. Davies, Middlesex; H. J. Davies, St. Mary's; R. K. Debenham, London; M. S. Dewhurst, Univ. Coll.; F. R. Dingle and R. A. M. Dyke, Guy's; R. G. Eastwood, Leeds; V. A. Edge, London; G. E. Ellis, St. Bart.'s; T. F. Everett, Middlesex; J. T. Fathi, London; V. L. Fisher, Guy's; C. S. Forrest, Manchester and Middlesex; D. B. Fraser, St. Bart.'s; J. H. Gibbens, St. Thomas's; O. P. Giles, Birmingham; J. Goldberg, London; R. T. Goodyear, Cambridge and Liverpool; D. L. Greig, Middlesex; J. M. Hall, King's Coll.; Constance I. Ham, Bristol; T. S. Hanlin, Manchester; A. W. Hanlon, Liverpool; W. D. Hasler, Middlesex; Irene D. F. C. Hastilow, Birmingham; N. H. R. Hatfield, St. Mary's; S. Helberg, London; A. Helmy, St. Thomas's; E. Herzberg, Heidelberg; A. R. Hill and H. F. Hiscocks, St. Bart.'s; E. F. Hottinger, St. Mary's; A. T. Howell, St. Thomas's; H. B. Howell, St. Bart.'s; O. R. Humphreys, London; D. J. C. Hutton, Middlesex; I. S. Jacobsz and M. E. M. Jago, Guy's; E. J. Jenkins, Birmingham; D. F. Johnstone and L. R. Jones, Guy's; B. Kaplansky, London; T. C. Kitching, St. Thomas's; Marjorie A. M. Lambert, Royal Free; H. Levy, St. Bart.'s; C. J. Lovering and A. C. MacLeod, Middlesex; C. T. Marshall, Manchester; G. C. Michael, London; F. C. Miller, Guy's; A. J. Moody, St. Bart.'s; C. F. Morrison, Guy's; R. H. Mortis, Charing Cross; I. S. Moscow, St. Bart.'s; K. V. N. Nair, London; R. G. Nethery and F. M. Newnham, Guy's; R. Paton, Middlesex; A. P. Pearce, London; A. D. Pegg, St. Thomas's; D. C. Prowse, Bristol; T. Rees, St. Bart.'s; J. T. C. Roberts, Liverpool; J. J. R. Robinson, St. Thomas's; Edith M. Ross-Johnson, Univ. Coll.; A. W. L. Row, St. Bart.'s; K. G. W. Saunders, A. de M. Severne, and E. M. Shackel, St. Thomas's; T. A. Shaw, Guy's; H. T. Simmons, Manchester; Sylvia M. T. Smith, Bristol; L. P. Spero, St. Mary's; I. P. Spurrell, Guy's; R. Stuart, St. Bart.'s; S. N. Taylor, Manchester; E. Thompson, St. Thomas's; P. G. Trafford, Guy's; Joan W. Urwick, Charing Cross; A. G. Walter, St. Thomas's; J. M. Wilder and C. R. Williams, London; C. L. Worthington and C. J. Wylde, Guy's; and Annie Yoffa, Cornell.

Midwifery.—D. A. Abernethy, St. Bart.'s; Agnes L. Adam, Royal Free; A. A. Anderson, Western Univ.; R. E. Artrick, Univ. Coll.; D. Aserman, St. Thomas's; H. M. H. Ashwin, Guy's; A. Ashworth, Liverpool; H. Y. Awad and H. M. Ayres, St. Thomas's; M. M. Baird, Oxford and Guy's; C. W. Bamford, London; Margaret A. Bannerman, Royal Free; A. K. Basilios, Birmingham; J. R. Beagley, St. Bart.'s; I. C. P. Beauchamp, Guy's; W. D. Beck, Birmingham; W. R. Bennett, St. Mary's; Elizabeth E. Benson, Bristol; R. H. Bestawros, Cairo; A. T. Bettinson and C. E. G. Beveridge, St. Bart.'s; G. W. R. Bishop, Bristol; C. P. Blacker, Oxford and Guy's; Kathleen Blake, King's Coll.; N. W. Bolton, Manchester; R. N. Brandwood, Guy's; H. F. Brewer, D. A. Brigg, R. J. Brocklehurst, and C. W. Brook, St. Bart.'s; O. W. B. Browning, Univ. Coll.; the Hon. C. B. Buckley, St. Thomas's; Margaret A. L. Buckner, Univ. Coll.; Mathilde E. F. Bugnion, London; Eleanor G. Burdett, St. Mary's; Mary E. Campbell, Charing Cross; De L. Carey, St. Mary's; Enid A. Ceiriog-Cadle, Royal Free; J. W. Clare, Birmingham; L. M. Clark, King's Coll.; Muriel G. E. Clark, Charing Cross; Ella J. Cockram, King's Coll.; S. M. Coleman, St. Bart.'s; L. N. R. Comty, London; C. P. Craggs, St. Bart.'s; D. P. Crawford, St. Thomas's; Celia M. M. Culver-Evans, Royal Free; C. I. Davies, London; H. G. Davies, Guy's; G. H. Day, St. Bart.'s; Hilda C. Dean, Charing Cross; J. V. Dockray, Middlesex; J. L. C. Doyle, St. Bart.'s; D. C. Drake, Guy's; J. Y. Eccles, St. Thomas's; E. A. R. Evans, Liverpool; L. Fatti, Univ. Coll.; A. K. J. Finch, St. Mary's; Barbara Finch, Royal Free; Winifrede M. Fish, King's Coll.; M. G. Fitzgerald, St. Bart.'s; R. G. Flower, Leeds; R. M. Forsayeth and C. W. E. Frederick, London; H. E. Gamlen, Durham; J. H. Gibbens, St. Thomas's; T. R. Goddard, Univ. Coll.; Catherine E. I. Greenshields and R. I. Greenshields, Liverpool; B. J. Griffiths, Cardiff; T. W. Griffiths and C. J. Grosch, Middlesex; A. Gross, St. Bart.'s; R. G. Hall, Charing Cross; Constance I. Ham, Bristol; G. T. Hankey, Guy's; L. F. A. Harrison, St. Bart.'s; J. R. B. Hern, Guy's; E. Herzberg, Heidelberg; A. B. Hewlett, King's Coll.; A. E. Hill, Guy's; C. H. Hilliard, St. George's; G. S. Hirst, Leeds; E. O. Hoermann, Birmingham; J. E. Howie, Liverpool; D. B. Hughes, London; J. Hughes, Bristol; J. P. Huins, Birmingham; Dorothea A. C. Hunt, Royal Free; S. Hyman, Leeds; F. F. Imianitoff and D. Imber, St. Bart.'s; G. J. Jack, Boston; C. James, Middlesex; C. W. Jones, King's Coll.; W. H. M. Jones, Cardiff; H. Kessel, Guy's; Rachel I. Kessel, Charing Cross; W. R. Kusel, St. Thomas's; D. M. Lang, Guy's; C. N. Latham, Birmingham; M. C. Lavin, London; E. D. Lawrence, St. George's; D. F. Lawson, St. Thomas's; H. E. Lewis, Guy's; D. A. Lubbock, Univ. Coll.; A. C. Lysaght, Guy's; C. B. McArthur, Royal Free; E. H. Mackenzie, St. Thomas's; D. H. MacLeod, Middlesex; H. P. R. Mavor, St. Thomas's; J. A. A. Mekelburg, Guy's; G. C. Michael, London; M. L. Millard, Birmingham; C. G. Millman, King's Coll.; J. G. Milner, St. Bart.'s; H. P. F. Modder, St. George's; E. F. Molony, St. Bart.'s; Mary A. Monro, Royal Free; G. C. Morris, St. Mary's; Eileen S. Morris, Univ. Coll.; W. G. R. Morris, Bristol; Marjorie Murrell, Royal Free; H. W. Nicholson, St. Thomas's; W. B. Norcott, Guy's; Maud Obbard, Royal Free; B. V. O'Connor, Middlesex; D. Oliver, St. George's; J. N. D. O'Rafferty, Guy's;

A. B. Osbourne, St. Mary's; C. H. Parker, London; G. Paterson, St. Thomas's; O. L. Prosser, Liverpool; F. W. F. Purcell, St. Thomas's; J. E. Readman, London; Nellie H. Reynolds, King's Coll.; E. W. Riches, Middlesex; M. V. Roberts, London; Victoria A. Roberts, Royal Free; L. G. Robertson, Bristol; A. E. Ross, St. Bart.'s; Edith M. Ross-Johnson and D. J. L. Routh, Univ. Coll.; N. L. Russell, St. George's; K. Samaan, Manchester; H. J. Satchwell, Bristol; H. H. E. Schulz and E. M. Shackel, St. Thomas's; J. W. Schollum, Guy's; J. Shutt, London; C. F. J. Smith, St, Mary's; A. W. E. Soysa, King's Coll.; B. L. Steele, A. L. Stephen, and Catherine E. Stephen, Univ. Coll.; J. M. Sterling and Ruby O. Stern, Charing Cross; P. Subbaramayya, Madras; Sylvia Sworn, Univ. Coll.; J. E. Swyer, London; J. G. S. Thomas, Guy's; J. L. Thomas, Middlesex; O. Tobin, London; E. J. F. Topham, St. Bart.'s; Mary E. Tyars and K. H. Uttley, Univ. Coll.; J. N. J. L. Uys, St. Thomas's; B. P. Vakil, Univ. Coll.; R. A. Walsh and L. B. Ward, St. Bart.'s; E. C. Warner, Guy's; W. B. Webster, St. Bart.'s; W. S. Whimster, Guy's; F. L. White and J. W. Whitney, London; D. O. Williams, St. Thomas's; E. J. Williams, Cardiff; G. O. Williams, Liverpool; T. I. Williams, Guy's; Emily A. C. Wilson, Charing Cross; H. G. Wimbush, Guy's; Ada R. Winter, Univ. Coll.; F. H. Woolley, Bristol; S. Wray, Manchester; H. C. Wykerd, London; C. J. Wylde, Guy's; and M. Yankelovitch, Middlesex.

Fellowship of Medicine and Post-Graduate Medical Association.—A four weeks' course starting on Nov. 24th will be given at the Royal Waterloo Hospital for Women and Children in medicine, surgery, and gynæcology. The programme has special reference to diseases of the blood, nervous system, heart diseases, feeding of infants, &c. During the first fortnight in December the following courses will take place: The Royal Northern Hospital, in conjunction with the Royal Chest Hospital, will hold an intensive course in medicine, surgery, and the special departments; at the Infants Hospital there will be a special course dealing with the study of infants from every aspect, and at the Hospital for Diseases of the Skin (Blackfriars) there will be a short course in dermatology, including venereal clinics. Copies of the syllabus of each of the above-mentioned courses may be obtained on application to the secretary to the Fellowship, 1, Wimpole-street, London, W. 1.

Medical Women's Federation.—The autumn meeting of the Council of this Federation took place at Plymouth on Oct. 31st and Nov. 1st, under the presidency of Miss Frances Ivens, M.S., President of the Federation. The business meetings were held in the Council Chamber of the Guildhall, and the members received a friendly greeting from the Mayor at their first meeting. Among the matters under consideration were reports from the local associations on salaries in public health appointments. In the discussion on these, emphasis was laid on the importance of three years' experience in candidates appointed to such posts. The following motion, to be sent to the Minister of Health, was passed:—

> That in the opinion of the Council of the Medical Women's Federation, the doctors to be appointed as assistant medical officers of health (school medical officer, infant welfare and pre-maternity medical officer, tuberculosis or venereal diseases medical officer) should have had at least three years' post-graduate experience—to include more especially work bearing upon the appointments for which application is made, such as diseases in children, obstetrics and gynæcology, the study of venereal diseases, &c.

The possibility of securing the appointment of a medical woman on the Board of Control was discussed. It was felt that this would be very desirable, as under the present circumstances there is no woman at all who visits the insane, the two lay women who are on the Board visiting the mentally defective only. It was resolved:—

> That a committee be appointed to prepare evidence regarding the need for a medical woman Commissioner on the Board of Control, and to take steps to submit such evidence to the Royal Commission on Lunacy, now sitting, together with a list of suitable candidates.

Reports from subcommittees of the Federation and from representatives on committees of the British Medical Association and other outside bodies were received and considered. The recent action of the London County Council in making a regulation that all their women medical officers must resign their posts on marriage without possibility of reappointment was reported and was much deplored. It was felt to be a severe blow dealt at the freedom of medical women to exercise their profession. The matter was referred to the Standing Committee for the Defence of Married Medical Women, for consideration as to future action. An interesting discussion arose on the answers to a questionnaire which had been sent out several months ago to most of the hospitals in this country in order to ascertain as far as possible (1) what hospitals have medical women on their staff and in what capacity; (2) in which hospitals are medical women eligible for staff appointments; and (3) what hospitals have women on their board of management. 581 circulars of inquiry had been sent out, and 423 replies had been received.

Mr. Neville Chamberlain, Minister of Health, has appointed Mr. Douglas Veale, of the Ministry of Health, to be his private secretary, and Mr. A. N. Rucker to be his assistant private secretary.

Dr. Walter Elliot has been reappointed to his old post of Parliamentary Under-Secretary for Health for Scotland.

The Chelsea Hospital for Women has received from the executors of the late W. B. Hextall a grant of £1000 towards the £20,000 required for the completion of the nurses' home and the opening of additional wards. £6500 is now urgently required.

The Need for Extended Sickness Insurance.—A paper on this subject will be read by Lord Dawson in the lecture theatre of the School of Oriental Studies, London Institution, Finsbury Circus, on Nov. 17th at 5.30 P.M., under the auspices of the Insurance Institute of London.

Tuberculosis Society.—An ordinary meeting of this society will be held on Friday, Nov. 21st, at 8 P.M., at the house of the Society of Medical Officers of Health, 1, Upper Montague-street, Russell-square, London, W.C., when Mr. C. Goulden will read a paper on Tuberculosis of the Eye.

Medical Officers of Schools Association.—The annual general meeting of this Association will be held at 11, Chandos-street, Cavendish-square, W., on Friday, Nov. 21st, at 5 P.M. (tea 4.30 P.M.), when Dr. L. R. Lempriere, the President, will read a paper on Preventive Hygiene in Public Schools Based on Twenty Years' Experience.

Royal Dental Hospital of London.—The staff of this hospital is holding its annual clinical "At Home" at the hospital, Leicester-square, W.C., on Saturday, Nov. 22nd, at 2 P.M. Cases of special clinical interest which have come under observation and treatment during the past year will be shown and demonstrations given. The various departments of the hospital will also be open for inspection. The medical committee extend an invitation to any medical practitioners who may like to attend. Tea will be provided.

Hunterian Society.—A meeting of this society will be held at the Cutlers' Hall, Warwick-lane, E.C., on Monday, Nov. 17th, at 8.45 P.M., when Mr. Justice Horridge and Sir William Willcox will open a discussion entitled the Medical Witness. It is hoped that the following will take part in the discussion: Sir Francis Newbolt, K.C., Sir Edward Marshall Hall, K.C., Sir Bernard Spilsbury, Mr. J. A. Cairns (magistrate, Thames police court), Mr. Freke Palmer, and Dr. Spurgin. Fellows are reminded that they may bring non-medical guests to this meeting.

London School of Hygiene and Tropical Medicine.—The Langley Memorial Prize has this year been awarded to Dr. P. S. Selwyn-Clark, M.C., D.P.H., of the West African Medical Service, for his monograph on Small-pox in the Negro and Negroid Tribes of British West Africa, with special reference to the Gold Coast Colony. The prize was founded by the friends of the late Dr. W. H. Langley, C.M.G., principal medical officer of Southern Nigeria, to commemorate his work, and this is the first year of award.

Royal Faculty of Physicians and Surgeons, Glasgow.—The annual meeting of the Faculty was held on Nov. 3rd, when the following office-bearers were appointed:

President: Dr. T. K. Monro. Visitor: Mr. J. H. Pringle. Treasurer: Dr. J. H. MacDonald. Hon. Librarian: Dr. E. H. L. Oliphant. Councillors: The President (ex-officio), the Visitor (ex-officio), the Treasurer (ex-officio), the Hon. Librarian (ex-officio), Dr. James A. Adams, representative to the General Medical Council (ex-officio), Mr. J. Mason Noble, Dr. W. G. Dun, Dr. A. Freeland Fergus, Dr. J. M. Munro Kerr, Mr. Thomas Kay, Mr. R. M. Buchanan, Dr. G. H. Edington, Dr. John Henderson, Dr. H. L. G. Leask, and Mr. R. Barclay Ness.

Society of Members of the Royal College of Surgeons of England.—The society announces that the following resolution will be moved on Nov. 20th at the annual general meeting of the Fellows and Members of the Royal College of Surgeons of England, to be held at the College, Lincoln's Inn-fields, London, W.C., at 3 P.M.:—

> "That this Thirty-seventh Annual Meeting of Fellows and Members again affirms the desirability of admitting Members to direct representation upon the Council of the College; moreover, this meeting requests that the President shall hereupon reply in detail to the two resolutions passed at the last annual meeting, and that he shall also state whether his Council has seriously considered any means whatever whereby the collective views of Members of the College may be ascertained on matters affecting their interests as Members."

This resolution will be moved by Dr. W. E. A. Worley and seconded by Dr. M. I. Finucane.

At a meeting of the Royal Geographical Society on Nov. 10th, Major R. W. G. Hingston, I.M.S., speaking of the possibilities of reaching the summit of Mount Everest, expressed his own conviction that though the physiological difficulties were severe, they could be overcome.

South African Institute for Medical Research.—The executors in the estate of the late Mr. A. W. Bannerman, of Johannesburg, have donated a sum of £1000 to this institute to be utilised in the prosecution of some line of medical research, having as its aim the improvement of the welfare of the native races of South Africa.

East India Association.—A meeting of this association will be held on Monday, Nov. 17th, at 3.30 P.M., at the Caxton Hall, Westminster, S.W. 1, when Major-General Sir Gerald Giffard, I.M.S. (retd.), will read a paper entitled "Some Aspects of the Future of Medicine in India." Surgeon-General Sir R. Havelock Charles, I.M.S. (retd.) will preside. Discussion is invited.

Royal Institute of Public Health.—The Harben lectures, which were to have been given on Nov. 24th, 25th, and 27th, by Prof. Edgar L. Collis, Talbot Professor of Preventive Medicine, University of Wales, on Phthisis and Industrialism (National and Occupational), with Reference to other Infectious Diseases, have unavoidably been postponed.—The next congress of the Royal Institute of Public Health, on the joint invitation of the corporations of Brighton and Hove, will be held in those boroughs from Wednesday, May 27th, to Monday, June 1st, 1925 (Whitsuntide).

Royal Commission on National Health Insurance.—The fifth meeting of this Commission was held at the Home Office, Whitehall, on Nov. 6th, Lord Lawrence of Kingsgate being in the chair. Mr. L. G. Brock, assistant secretary, and Dr. Smith Whitaker, senior medical officer, both of the Ministry of Health, were examined further on a variety of matters relating to the administration of medical benefit—e.g., the conditions of service for insurance practitioners, the supply of drugs and appliances, the various medical funds, the scale of payment for medical services and drugs, the method of selection of doctors by insured persons, the mileage payments, &c. The Commission announce that the oral evidence given at the meeting of Oct. 23rd, 1924, is now on sale in proof form (1*s.* 6*d.*) at H.M. Stationery Office, Kingsway, London, W.C. 2.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Burlington House, W.
Thursday, Nov. 20th.—At 4.30 P.M.
Papers.—J. Barcroft, M. L. Anson, A. E. Mirsley, and S. Oinuma: The Correlation between the Spectra of Various Hæmoglobins and their Relative Affinities for Oxygen and Carbon Monoxide. H. R. Hewer: On Certain Abnormalities occurring in the Pituitary of the Frog. (Communicated by Prof. E. W. MacBride.)
Papers to be read in title only.—A. Howard: The Effect of Grass on Trees. (Communicated by Sir John Russell.) J. W. Pickering and F. E. Taylor: Blood Coagulation, Anti-Coagulants and Hæmolysis. (Communicated by Prof. W. D. Halliburton.) R. J. Ludford: The Distribution of the Cytoplasmic Organs in Transplantable Tumour Cells: with special reference to Dictyokinesis. (Communicated by Prof. J. P. Hill.) E. Ponder: On the Balloon-like Structure of the Mammalian Erythrocyte. (Communicated by Sir E. Sharpey Schafer.) V. B. Wigglesworth: Uric Acid in the Pieridæ; a Quantitative Study. (Communicated by Prof. F. G. Hopkins.) G. Lindsay Johnson: Contributions to the Comparative Anatomy of the Reptilian and the Amphibian Eye, chiefly Based on Ophthalmological Examination. (Communicated by Dr. H. Gadow.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Nov. 18th.

GENERAL MEETING OF FELLOWS: at 5.30 P.M.

PATHOLOGY: at 8.30 P.M.
T. Lumsden: Observations on Cancer Cells in vitro.
J. A. Murray: Hypersensibility of the Tissues to Cancer.
A. Fleming: The Effect of Various Chemicals on the Leucocytes.

Wednesday, Nov. 19th.

HISTORY OF MEDICINE.
No Meeting of the Section will be held on Wednesday, Nov. 19th, but the President and Council of the Medical Society of London have invited the Members of the Section to attend the "Lloyd Roberts Lecture," which will be given on Nov. 19th at 5 P.M., at the House of the Medical Society, 11, Chandos-street, W. 1, by Dr. Herbert Spencer on "The Renaissance of Midwifery."

Thursday, Nov. 20th.

DERMATOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases:
Dr. H. C. Samuel: Case for Diagnosis.
Dr. H. W. Barber: Multiple Sarcoid with Lupus Vulgaris.

Friday, Nov. 21st.

ELECTRO-THERAPEUTICS: at 8.30 P.M.
Paper:
Dr. Rist (of Paris): The Respiratory Displacements of the Mediastinum and some Allied Phenomena.

MEDICINE.
Members of the Section of Medicine are specially invited to attend this Meeting.

THE MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. 1.
Wednesday, Nov. 19th.—5 P.M., Dr. Herbert R. Spencer: The Renaissance of Midwifery. (Lloyd Roberts Lecture.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.
Thursday, Nov. 20th.—8.15 P.M. (At the London School of Hygiene and Tropical Medicine, Endsleigh-gardens, Euston-road.) A laboratory meeting, and demonstrations by Major E. E. Austen, Drs. W. Broughton-Alcock, H. B. Day, Captain W. H. Dye, Drs. Drbohlav, H. M. Hanschell, W. E. Haworth, Colonel S. P. James, Colonel Clayton Lane, Mr. Ll. Lloyd, Drs. Manson-Bahr, Colonel Marrian Perry, Drs. J. Harvey Pirrie, H. H. Scott, Surg.-Commander T. B. Shaw, and Mr. A. L. Sheather.

THE TUBERCULOSIS SOCIETY, 1, Upper Montague-street, Russell-square, W.C.
Friday, Nov. 21st.—8 P.M., Mr. Charles Goulden: Tuberculosis of the Eye.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
Monday, Nov. 17th, to Saturday, Nov. 22nd.—West Lecture Hall, Royal Society of Medicine, 1, Wimpole-street. Lectures arranged by the Fellowship of Medicine and open to all members of the profession. At 5.30 P.M., Mon., 17th, Mr. Cyril A. R. Nitch: Cancer of the Intestine. Wed., 19th, Mr. W. Sampson Handley: Cancer of the Breast. Fri., 21st, Mr. H. S. Souttar: Carcinoma of the Œsophagus.—St. John's Hospital for Diseases of the Skin, Leicester-square, W.C. Daily demonstrations, pathological demonstrations, and lectures on Tuesday and Thursday by Dr. A. Whitfield. Third week.—St. Mark's Hospital for Diseases of the Rectum, City-road, E.C. Special Intensive Course in Proctology, including lectures, demonstrations, and operations. Second week.—Chelsea Hospital for Women, Arthur-street, S.W. Special Course in Gynæcology, consisting of lectures, demonstrations, and operations. First session on Friday, the 21st, at 2 P.M., lecture by Mr. Comyns Berkeley, operations, and demonstration.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
Monday, Nov. 17th.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Mr. Bishop Harman: Eye Dept.
Tuesday.—10 A.M., Medical Registrar: Clinical Methods. 11 A.M., Dr. McDougal: Medical Electricity. 12 noon, Dr. Burrell: Chest Cases.
Wednesday.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 11 A.M., Mr. Simpson: Gynæcological Wards. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
Friday.—12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.
Saturday.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Tuesday, Nov. 18th.—4.30 P.M., Mr. E. S. Pierrepont: Pyorrhœa and Related Conditions.
Friday.—4.30 P.M., Dr. J. B. Alexander: Mediastinal Affections, their Diagnosis, Prognosis, and Treatment.
Daily: Medical and Surgical Clinics and Clinics in the various Special Departments, Surgical Operations, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Nov. 20th.—4 P.M., Dr. Robert Hutchinson: Convulsive Disorders in Infancy and Childhood.

ST. JOHN'S HOSPITAL, Leicester-square, W.C.
TUESDAY, Nov. 18th.—5 P.M., Dr. A. Whitfield: Diseases due to Fungi.
THURSDAY.—5 P.M., Dr. A. Whitfield: Diseases due to Fungi.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, Nov. 17th.—(At the Shaw-street Hospital.) Dr. Willett: Dysmenorrhœa.
TUESDAY.—(At the Maternity Hospital.) Miss Ivens: Induction of Premature Labour.
WEDNESDAY.—(At the St. Paul's Eye Hospital.) Mr. H. Haward Bywater: Methods of Eye Examination.
THURSDAY.—(At the St. George's Hospital.) Dr. F. H. Barendt: Skin Cases.
FRIDAY.—(At the Eye and Ear Infirmary.) Dr. E. Stevenson: Eye Injuries and their Treatment.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
TUESDAY, Nov. 18th.—4.15 P.M., Mr. F. H. Westmacott: Deafness, Curable and Incurable.
FRIDAY.—4.15 P.M., Mr. A. H. Burgess: Some Points in the Surgery of the Biliary Tract.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES. (At 3.30 P.M.)
TUESDAY, Nov. 18th.—(At the Royal Infirmary.) Mr. Pooley: The Ocular Causes of Headache.
FRIDAY.—(At the Children's Hospital.) Mr. P. Reckless: Cervical Adenitis.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.
WEDNESDAY, Nov. 19th.—3.15 P.M. (at the Town Club, Swindon), Mr. L. E. Claremont: Care and Treatment of Children's Mouths.

THE ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.
TUESDAY, Nov. 18th.—4 P.M., Prof. Herring: The Physiology of the Kidney (continued).

CHADWICK PUBLIC LECTURES.
WEDNESDAY, Nov. 19th.—8 P.M. (at the Royal Institute of British Architects, 9, Conduit-street, W. 1), Prof. J. B. Cohen: Smoke: Cause, Nature, Effects and Methods of Prevention.

ROYAL INSTITUTE OF PUBLIC HEALTH, Russell-square, W.C.
(Course of Lectures on the Health of the Commonwealth.)
WEDNESDAY, Nov. 19th.—4 P.M., Prof. Louise McIlroy: The Influence of Antenatal Care upon Infant Welfare and Mortality.

THE PEOPLE'S LEAGUE OF HEALTH. Course of Lectures on the Mind and What We Ought to Know About It.
(At the Medical Society of London, 11, Chandos-street, W.)
MONDAY, Nov. 17th.—6 P.M., Sir Robert Armstrong Jones: Fatigue and Sleep.

Appointments.

CATHCART, W. B., M.B., B.Ch. Dub., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Swaffham District of the County of Norfolk.

CLAUSEN, R. J., M.B., B.S. Lond., Anæsthetist to the Queen's Hospital for Children, Hackney-road.

MAINGOT, RODNEY, F.R.C.S. Eng., Surgeon with Charge of Out-patients, Royal Waterloo Hospital for Children and Women.

SHINNIE, A. J., M.D. Aberd., D.P.H., Medical Officer of Health for the City of Westminster.

THOMSON, J., M.B., Ch.B., M.R.C.P. Edin., Assistant Physician, Department Diseases of Children, Dundee Royal Infirmary.

Edinburgh Royal Infirmary: WIGHTMAN, A. R., M.B., Ch.B., BRODIE, P. M., F.R.C.S.E., MORRIS, G., M.B., Ch.B., SMITH, G. L. M., M.B., M.R.C.P.E., TODD, T. R. R., M.B., M.R.C.P.E., LOUDON, —, M.B., Ch.B., STRACHAN, —, M.B., Ch.B., MATHESON, A. R., M.B., M.R.C.P., HOULTAIN, W. F. T., M.C., F.R.C.S. Edin., MILLER, D., M.D., F.R.C.S.E., GRAHAM, —, F.R.C.S. Edin., SCOTT, —, M.B., Ch.B., BATCHELOR, R. C. L., F.R.C.S., LISTON, MARY F., M.B., Ch.B., Clinical Tutors and Senior Clinical Assistants. HERDMAN, DOROTHY P., M.B., Ch.B., DAVIES, H. W., M.B., Ch.B., GILCHRIST, A. R., M.B., Ch.B., ILLINGWORTH, C. F. W., M.B., Ch.B., SHEARER, D. A. M'M., M.B., Ch.B., STARKEY, —, M.B., Ch.B., M'LACHLAN, E. A. W., M.B., Ch.B., Clinical Assistants.

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth Infirmary, &c.—H.S. £200.
Bristol General Hospital.—Hon. Reg. to Throat and Nose Dept.
Cambridge, Addenbrooke's Hospital.—H.S. at rate of £130.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Anæsthetist. £50.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—H.P. Two H.S.'s and Obstet. Asst. at rate of £50 each. Also Asst. S.
Evelina Hospital for Children, Southwark, S.E.—H.S. at rate of £120.
Hackney Union Infirmary.—Jun. Asst. M.O. £350.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Ophth. S.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each £50.
London Royal Free Hospital School of Medicine for Women, Hunter-street, Brunswick-square, W.C.—Third Asst. in Obstet. and Gynæcol. Dept. £270.
Manchester Royal Infirmary.—Res. M.O. £260.
Manchester, St. Mary's Hospitals.—Three H.S.'s for seven months at rate of £50.
Metropolitan Ear, Nose, and Throat Hospital, Fitzroy-square, W. Asst. S. and Clin. Assts.
Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Jun. Res. M.O. £100. Also Asst. Cas. O. at rate of £100.
Miller General Hospital, Greenwich-road, S.E.—Res. Cas. O. £150.
Nottinghamshire County.—M.O.H. £1200.
Oxford County and City Mental Hospital, Littlemore, near Oxford.—Second Asst. M.O. £350.
Richmond, Surrey Royal Hospital.—Asst. H.S. £100.
Rochester, St. Bartholomew's Hospital.—H.P. at rate of £200.
Rousay and Egilshay Parish, Orkney.—R.M.O. £400.
Royal College of Surgeons of England.—Election to Court of Examiners.
Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £150. Cas. O. £100. Asst. Cas. O., Obstet. Asst., Obstet. H.S. Also H.P. and H.S. All £50.
St. Bartholomew's Medical College, E.C.—Demonstrator of Physiology.
Salford Royal Hospital.—Res. Surg. O. £200.
Sheffield, Jessop Hospital for Women.—Sen. Res. M.O. £250. Also two Asst. H.S.'s at rate of £100.
Somerset County Council, Quantock Lodge Tuberculosis Sanatorium.—Res. Med. Supt. £739 12s.
Truro, Royal Cornwall Infirmary.—H.S. £170.
Virol Scholarship in Hæmatology. £200.
West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Asst. P., Laryngologist. Also Otologist.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Non.-Res. H.S. at rate of £150.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.
York County Hospital.—H.P. £150.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Lancaster, Lancs; Eastwood, Notts; Heanor, Derby; Hawarden, Flint.

Births, Marriages, and Deaths.

BIRTHS.

BROOME.—On Nov. 6th, at Port View, Seaview, I.W., the wife of Dr. F. C. Sedgwick Broome, of a son.

KEMP.—On Nov. 6th, to Dr. and Mrs. P. Rowland Kemp, of 62, Leytonstone-road, E. 15.—a son.

MURPHY.—On Oct. 7th, at Rawalpindi, the wife of Major L. Murphy, R.A.M.C., of a daughter.

MARRIAGES.

KNAPP—SHAW.—On Nov. 5th, at the Royal Chapel of the Savoy, Lieut.-Colonel H. H. G. Knapp, M.A., M.D., I.M.S., to Mabel Enid, only daughter of the late A. G. Shaw, and of Mrs. Shaw, of Bournemouth West.

LOW—RAWSON.—On Nov. 1st, at St. Stephen's, Vincent-square, Harold Low, M.B., of Evelyn-gardens, to Annie Rawson, of Vincent-square.

DEATHS.

DOWNES.—On Friday, Nov. 7th, 1924, Thomas William Hardwicke Downes, M.R.C.S. Eng., L.R.C.P. Lond., of Ludlow, Shropshire, aged 49.

HELLIER.—On Nov. 8th, 1924, at 5, Bank View, Stainbeck-lane, Leeds, John Benjamin Hellier, M.D., aged 71.

LAMPORT.—On Oct. 30th, at Lancaster, Henry Christopher Lamport, M.B., C.M., in his 63rd year.

MOSS.—At Imerimandroso, Madagascar, on Nov. 1st., C. F. Arrowsmith Moss, M.D. Edin., aged 59 years.

NORTH.—On Oct. 31st, at sea, on board the s.s. *Leicestershire*, of which he was surgeon, as the result of war wounds, Thomas Stanley North, M.B., B.S. Lond., F.R.C.S. Eng., aged 27, eldest son of Thomas North, F.R.C.S.I., of New Southgate and 28, Welbeck-street, W. 1.

TATHAM.—On Nov. 8th, at the White House, Oxted, Surrey, John Francis Walkingame Tatham, M.A., M.D., in his 81st year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

JAMAICA AS A HEALTH-RESORT.

BY JOSEPH GEOGHEGAN, M.D. EDIN., F.R.C.S. EDIN.,
KINGSTON, JAMAICA,
LATE SURGICAL SPECIALIST, ULSTER DISTRICT, R.A.M.C.;
SURGICAL SPECIALIST, MINISTRY OF PENSIONS,
ULSTER REGION.

DESPITE historic precedent set by Ponce de Leon, the West Indian Islands have been little used as health resorts. Yet for this purpose certain of them possess decided qualities to attract and benefit the invalid, and they adduce in addition possible avenues for a very pleasant holiday. Amongst them none present a more gracious aspect than Jamaica. As it is distant but 17½° from the equator, the general climatic conditions of Jamaica are consequently those of its geographical position, but they are favourably modified in certain directions.

Lying in the midst of the Caribbean Sea, the island is surrounded by a wide belt of water, and the unequally altering thermal properties of these elements set up constantly interchanging currents of air. Thus a temperature by day otherwise tropical is mitigated and relieved by a steady breeze which blows from the sea all the year round, and the nights are refreshed by the deliciously cool land breeze coming down from the hills which form the backbone of the island. These mountains, rising sharply from the coast, run in irregular ridges from west to east, rising to heights of over 7000 feet. It is from those altitudes that the land breeze comes with such effect as to admit of a diurnal variation in temperature of some 15° or 16° F.; so marked and so sudden is the evening fall of the thermometer that it is considered wise to adopt precaution against chill, particularly after exercise.

Jamaica's Two Climates.

The curiously broken configuration, aptly caught by Columbus when he crumpled up a piece of paper to represent the island, is one of the main causes of the singular and striking beauty of Jamaican scenery, and in addition endows it with virtually two climates. There is the coastal climate, more attractive along the picturesque north side, where the trade wind coming off the sea is locally known as the "doctor," and there is the hill climate. The former is warmer, soothing and relaxing; drier, more equable, and heavily ozone-laden. The hill resorts, from 2000 to 3000 feet in altitude, are more bracing with their lower thermal range, lower barometric pressure, and stronger breezes. Both regions have their advantages and provide in alternation pleasant and health-giving variety.

The heat of the tropic sun is further tempered by the humidity of the air, which is high, consequent on the large neighbouring areas of water. The mean figure is 78 for the winter months, but due allowance being made for local variation the climate is not damp. The rainy seasons of October and April are sharp, but the rest of the year is distinguished by constant bright sunny weather of a regularity as welcome as it is novel after the vagaries of the English climate.

The geological surface composition of Jamaica is very largely a white limestone, whose porous, absorptive nature, despite the many streams from which the island derives its name,[1] constitutes the advantages of a dry, well-drained soil, and assists in maintaining this balmy, agreeable, and altogether charming climate. More conjectural but none the less helpful adjuvants are the extreme purity of the air and the intensity of the light. The scope of heliotherapy is too uncertain to permit of dogmatic precision, but of the physical and psychical benefit of the cheerful conditions of clear pure air and bright constant sunlight there can be no doubt. The mean temperature for the winter months, November to March inclusive, is in Kingston 76·5° F. The capital is, however, from its position on the south side, away from the breezy benefit of the trades, one of the hottest places in the island; the corresponding figure for some of the favourite hill resorts is some 8° or 10° lower.

Contrast with certain non-tropical resorts may clarify the salient points. Nice, with a proverbially mild climate, has a mean winter temperature of 49°. Madeira, which, like Jamaica, is also favourably affected by its geographical situation and structure, has a mean humidity of 75, and a mean annual temperature of 65°. The mean temperature in Cairo for January is 53°, Egypt generally being favoured by the famous "Etesian" wind and having a singularly dry climate (the mean humidity at Wadi Halfa is only 32).

The subtle metabolic variation induced by a change of climate has long been known empirically to react favourably on conditions of ill-health. Many states of delicate health, delayed convalescence, general breakdown, anæmia, tardy recovery from operation, &c., will be materially improved by any attractive holiday, be it Egypt, Nice, Madeira, or Jamaica, a reasonable allowance for the personal equation being alone required. There are, on the other hand, a numerous series of diseases whose optimum climate is a matter of care, consideration, and forethought.

The Virtues of the Island.

The leading features of the Jamaican climate as briefly indicated above will, no doubt, readily suggest its utility as a health resort. Certain affections show a singularly satisfactory response; they fall naturally into groups. For that group which comprises cardiac, vascular, or renal defects, the warmer sea coast with its high excess of ozone is more suitable. The alleviation of distressing symptoms obtained by even a short residence is surprising, and is only partly due to the absence of exposure to chill or to unnecessary variation in surrounding temperatures. The better distribution of the circulation, due to peripheral vascular relaxation and dilatation consequent on the warm atmosphere, not only relieves the kidneys by increasing skin excretion, but directly affects arterial tension.

It is curious to notice that Hans Sloan, M.D., "Body-Physician to the Duke of Albemarle," remarked some 200 years ago[2] on this same point, referring to the beneficial effects of the climate of Jamaica on plethoric, sanguine individuals, by which he undoubtedly intended those conditions covered to-day by the term "blood pressure." This observer further noted, with indubitable truth, a distinct prolongation of life in aged Europeans, and their decidedly greater vitality both of body and mind, their increased muscular and nervous capacity.

This warm marine climate is further well adapted for rheumatic troubles—arthritic or muscular—assisted, if necessary, by one or other of the mineral baths. The hill resorts presenting a mountain climate of a cool, keen, invigorating nature, possess great advantages for certain diseases of the respiratory tract. Those of the dry catarrhal type find residence here very suitable, but it is not recommended for cases of a moist, exudative nature, nor for pulmonary tuberculosis. Further experience but confirms an opinion already indicated as to this last disease in the tropics.[3] The bracing effect of the preliminary sea voyage, most of which is spent in warm weather, must not be overlooked. A condition which often favourably responds to residence in the island is insomnia. I am quite unable to account for the soporific effect of the climate, but have been notably impressed.

It may not be out of place to refer to a curious fact, that the normal differential count of the individual here shows a relative lymphocytosis at the expense of the polymorphs the percentage of each being much closer than at home. Discussion of the causation of this change is irrelevant. The novel surroundings, the rich and varied diet, predominantly vegetarian, and the social amenities of a hospitable island coöperate with the physical change by affording the distractions always necessary in delicate or debilitated conditions, but particularly of aid when there is any nervous element.

Mineral Springs.

Jamaica is further fortunate in possessing two valuable mineral springs, though neither is yet developed as hydropathic establishment to that extent which it is hoped the future will provide. Their admirable qualities are much used locally. Bath is hot (128° F.), sulphurous, and non-purgative; its advantages lie in the treatment of neuritic and arthritic conditions, or cutaneous lesions. The other at Milk River, is warm, saline, and purgative, and is also highly radio-active. It can be strongly recommended for the disturbed metabolism arising from auto-intoxications for gout, rheumatism, cirrhosis, and the like.

Almost any part of the island can be reached by a series of excellent motoring roads. The various sports, tennis golf, fishing, shooting, polo, cricket and football, are all popular local pastimes. Our insular attachment to certain foreign climes might with wisdom be subordinated to the welfare of the undeveloped resources of the Empire. It is hoped, therefore, that patriotism will stimulate, as self interest would urge, the greater exploitation of the charm of the Queen of the Antilles.

SOME PROBLEMS OF ASSURANCE MEDICAL PRACTICE.

IN his able and very comprehensive presidential address to the Assurance Medical Society on Nov. 5th Dr. G. Grahamsley Howitt referred to some problems raised by modern laboratory methods of investigation and by the experience of conditions originating during recent war service. Of these the most urgent and practical was that of the significance of glycosuria and its relation to true diabetes mellitus on the one hand, and to less serious disturbances of metabolism on the other.

Glycosuria as the Only Symptom.

Speaking from the standpoint of the examiner for life assurance Dr. Howitt said: "Assurance practitioners so often get the beginnings of diseases, slight signs only, and so very rarely typical text-book cases. Glycosuria, for example, is often found with no other signs or symptoms. It may be possible to get a blood-sugar test done—I have had a number of cases now—and so clear up the question whether the glycosuria indicates the beginning of the diabetes or not, and also determine whether there is some other reducing substance or not. But here again we have a new problem, for the case may turn out to be one of the kind which has almost as many names as has the albuminuria of adolescents—renal glycosuria, renal diabetes (there is no diabetes), negligible glycosuria, diabetes innocens. Dr. George Graham speaks of these as 'patients who excrete dextrose, but do not suffer from diabetes mellitus.' They give normal results to the blood-sugar test, they excrete sugar in the urine, but the level of the blood-sugar is normal or below normal. 'They feel unwell if dieted at all strictly.' At any rate, if renal glycosuria is suspected, somewhat elaborate tests by diet and examination of the urine are required to make sure.

"This necessary procedure negatives its employment in life assurance, except in very rare and exceptional cases, but one may be called upon to deal with them in cases where a man for his own sake has undergone these elaborate tests. Graham remarks: 'The disease as an entity is a new one,' and 'the cases having been only fully worked out since 1916.' They seem to be very limited in number. So far as I can judge, if one does come across a case under the circumstances I have mentioned, it could possibly only be dealt with at present on the lines of a heart case in good condition, with an adequate addition or on special terms. Possibly now that the condition has been investigated, more will be heard of it. The subjects do not seem to do well in hot climates.

"There still seems some difference of opinion about this defect. Marsh says: 'Most cases recorded are really cases of ordinary diabetes'; however, this was in 1921 and things march rapidly at the present time. For myself I feel inclined to seek safety in caution and to treat them as in diabetes unless a differential diagnosis can be worked out.

"Speaking of diabetes, one cannot help wondering whether in time there will not arise cases in which, by modern treatment of diet and insulin, the cells of the islands of Langerhans will be sufficiently restored to function as to enable the patient to do without treatment. That, of course, can hardly happen for some time yet, but it seems possible. Later on we may have them coming up for examination."

After-effects of Gassing.

Dr. Howitt then went on to the after-effects of gassing and to the problems of prognosis in those who had undergone it. "Cases still keep presenting themselves, and will continue to do so, I suppose. There is a good deal of literature on the subject, but little guidance as to what to expect in the future. An enormous amount of experimental work was done during the war, particularly in the U.S.A. by Warthin and Weller, and Winternitz. Winternitz expresses the opinion, as the result of his experiments on dogs, that 'a soldier who has recovered from the acute effects of gassing should be regarded as an individual with damaged lungs.' A later opinion by Arthur F. Hurst is to the effect that a considerable time elapses before complete restoration to health occurs, and it is still doubtful whether a greater or less degree of permanent incapacity may not sometimes follow. These were opinions based on the more or less immediate effects, and apply to pulmonary irritants.

"One may dismiss those cases where the effects were so slight as to be only temporary and those who were so seriously damaged as to become permanent invalids. The immediate effects were to produce an inflammatory and sometimes destructive condition of the respiratory organs, the extent of which varied according to the type of gas and the amount inspired.

"It appears that the fear that pulmonary tuberculosis would be a common result has not been realised, but perhaps the time is yet early to come to a definite conclusion. Raymond and Guilham, taking 162 cases, found only two cases of 'true pulmonary tuberculosis,' but 27 of recurrent simple bronchitis and 31 with emphysema in addition. They are of the opinion that 'the development of actual pulmonary tuberculosis after gassing is extremely rare.' This is borne out by Dr. T. E. Sandall in an investigation of the record cards of 83 pensioners. He found 46 per cent. with evidence of emphysema or chronic bronchitis or both, so that 'the popular impression that pulmonary tuberculosis is a frequent sequela is not borne out'; but if recovery does not take place at an early stage, the later effects, if not permanent, are at any rate of long duration. Tachycardia is found in 45 per cent. Thompson Campbell describes two pathological conditions—bronchitis with absence of dullness on percussion, no increase of V.R. or vocal fremitus with harsh or puerile respiratory murmur, prolonged respiration, coarse rhonchi and small muco-crepitant râles, if the bronchioles or alveoli are involved. The other condition is a sclerosis or slight fibrosis with diminution of percussion over the lobe, deficient air entry, harsh and puerile respiratory murmur, without increased tactile vocal fremitus or V.R. as in tuberculous consolidation. The pulse-rate is not accelerated, the temperature does not suggest tubercle, and there is wasting and debility. Shortness of breath is greater than would exist with a T.B. lesion of limited extent.

American Experience.

"Hermon Harrison Cole, in U.S.A., says the 'pathological changes are usually found toward the central and lower parts of the chest rather than the apices.' . . . There is a general and steady tendency toward recovery with decrease of physical disturbance. . . . War gassing has little to do with the development of late pulmonary tuberculosis. . . . In gassed patients, who later develop tuberculosis, it usually runs a less severe course with less tendency to serious complication than non-gassed patients. . . . The differential diagnosis from pulmonary tuberculosis is becoming more satisfactory, through recognition of rather dependable diagnostic points: of which temperature, progressive loss of weight, tendency to hæmorrhage, are most important. . . . In no single case from gas alone has a history of large hæmorrhage been given. . . . The ultimate outlook of gassed patients with or without tuberculosis is far from settled. The effect of gassing on life expectancy can be determined only by further experience.'

"This latter seems the general opinion and the inferences which may be drawn from these experiences are—that tuberculosis is not a usual sequel of gassing; that it may be necessary to make a differential diagnosis between pulmonary tuberculosis and the results of gassing; that the common results which may persist are chronic bronchitis and emphysema, a sclerosis or fibrosis, and that there is a general and steady tendency to recovery. Personally I have seen a goodly number of people who have been gassed, but all seemed to have recovered, showing no physical signs, or at most giving only a history of having an occasional cough. In only one did I find a patch over the middle lobe on the right side where there was somewhat harsh breathing. I could not satisfy myself that there was any alteration of the percussion note. The man had sometimes a morning cough, but played a good deal of tennis, took a lot of other exercise, and looked fit. He had been examined a year or two before, and was then said to have shown signs of bronchitis and emphysema. I felt inclined to take him on an Endowment Assurance with an extra."

WAR ON PESTS.

A VIGOROUS war on pests was declared on Friday, Nov. 7th, at the annual dinner of the recently incorporated College of Pestology (Bedford-square), held at Pagani's Restaurant, the pests particularly singled out for attack being the rat, the house-fly, the cockroach, the tsetse, the bilharzia, the death-watch beetle, the grey squirrel, the sparrow, and the mosquito, Col. Cuthbert James, M.P., Chairman of the College, presiding. Sir James Crichton-Browne insisted that the College must concentrate on the rat, which, despite every effort, was as aggressive as ever. Until recently, he said, the only use of the rat had been the skin, but modern science was now employing the white rat as a sort of living test-tube for feeding experiments. At the present moment, he remarked, the Hanoverian rat was making its way in huge contingents from the country to its winter quarters in London, while its alleged function as a scavenger was completely exploded. The mosquito, he pointed out, was a permanent menace to mankind wherever it existed. In spite of all the precautions taken two ships had recently arrived in British ports heavily stricken by malaria and affording an ample supply of material for British mosquitoes to distribute should they get at it. He announced that the College had recently appointed a committee under the able chairmanship of Sir James Simpson to consider what steps should be taken for the banishment of the mosquito from Great Britain, and that a gold medal was to be given for the best essay on the subject. Further, in response to a suggestion by Dr. Andrew Balfour, of the London School of Hygiene, a panel of applied zoology had been formed, which would collect specimens of pests from all parts of the country and would institute research in various directions. Lieut. Alfred E. Moore, founder and hon. director of the College, spoke particularly of the importance of eliminating the cockroach and the grey squirrel. The latter was merely a tree-climbing rat and was ousting the beautiful red squirrel and doing immense damage in fruit-growing districts. Prof. Maxwell Lefroy spoke of the injury done by the common house-fly, charging it with carrying diseases that in this country alone caused between 15,000 and 20,000 deaths every year. In this connexion Major P. T. Wessel, an hon. secretary of the College, stated that it was proposed early next year to organise a fly "swatting" week. It was also argued that the friends of the College could do useful work by encouraging the use of the sparrow, which was a very destructive pest, as an article of diet in restaurants.

A further indictment of the rat was pronounced, and methods of minimising the rat menace were outlined, by Mr. Mark Hovell at the Chadwick public lecture delivered at the Barnes Hall, 1, Wimpole-street, W., on Nov. 10th, Sir William Collins presiding. He said that although rats cost this country £1,000,000 sterling per week, continuous war was not waged against them. There were spasmodic efforts to reduce the number of rats, such as Rat Weeks, but by the time the next Rat Week came round those which escaped the previous slaughter had produced many millions of descendants. He said that there would be no decided diminution in the number of rats throughout the country until continuous trapping was enforced. A 5-inch rabbit-trap was in many ways the best steel trap, but where a cage trap was required, the "Terrier" death run trap was by far the most efficient. Both could be provided with a cover, and also a signal to show if the trap was set or sprung. The presence of a "few" rats was usually disregarded, but a pair and their descendants at a low computation would produce in 11 months 1130, and in 13 months 3050. Farmers usually allowed their stacks to be rat-infested, but in six months 1132 rats would eat and waste wheat to the equivalent of 2329 quartern loaves, 306 bushels of sharps, and 723 bushels of bran. Rats conveyed trichinosis, foot-and-mouth disease, infectious jaundice, mange, ringworm, distemper, rat-bite fever, and last, but not least, plague, which during last March in the Punjab alone caused 25,000 deaths. More cases of plague occurred in this country than the public were aware of, and but for very careful supervision at ports there might be serious outbreaks. To reduce the number of rats to a minimum all unnecessary openings into houses or buildings should be closed, as well as traps being kept set continuously throughout the year. If pig-keepers and poultry-keepers were registered, means could be taken to ensure these rat centres being efficiently dealt with. Virus, he said, had no advantage over the recognised poisons, and its use was strongly deprecated. County councils could obtain a considerable income by enforcing the Rats and Mice (Destruction) Act, 1919, using police stations as the centre at which information could be obtained or given.

PUBLIC HEALTH IN NYASALAND.

THE territory comprised in this Protectorate is a strip about 520 miles in length and varying from 50 to 100 miles in width. The area is roughly 40,000 square miles, or about one-third the area of the British Isles. The most southerly portion of the Protectorate is about 130 miles from the sea as the crow flies. The general health during 1923 was good. In the early part of the year there was an extensive outbreak of influenza, but the mortality was comparatively low. The native population was at the time suffering from famine, and this no doubt caused a higher mortality than would otherwise have been the case. There was a small outbreak of a mild type of small-pox in the Mlanje area; 13 natives contracted the disease. Isolation was carried out immediately and contacts were, as far as possible, vaccinated and kept under surveillance, and the outbreak soon died out. Three cases only of sleeping sickness were reported amongst the native population; all three died. There were a few cases of paratyphoid fever occurring amongst Europeans in Blantyre. During the year there were treated at the Government hospitals and dispensaries 635 Europeans and 99,522 natives, as against 522 and 41,633, respectively, in 1922. The increase in the number of European patients was due to the outbreak of influenza; and in the natives the increase was due to the establishment of rural dispensaries, which treated 61,650 new cases during the year, as compared with 11,600 in 1922. The climate of Nyasaland, in its essential features similar to that of the rest of Eastern Africa within the tropics, is necessarily diversified owing to variations in latitude, altitude, and general configuration of the terrain, presence or absence of rivers, forests, &c.; but as a large proportion of the Protectorate lies at an altitude of 3000 feet or more, the heat is not generally excessive. The monsoon commences to blow strongly in September in conjunction with the sun's increase in southerly declination, and the first rains may be expected any time after mid-October. From their commencement to the end ot December it is usual to experience violent thunderstorms and heavy precipitation in a few hours, followed by an interval varying from 1 to 15 or 20 days of intense heat. With the return of the sun from its southern limit of declination, the thunderstorms diminish in intensity and frequency, and are replaced by steady rain, January, February, and March being usually the wettest months as regards duration of rainfall as well as actual amount. After March the frequency and intensity of rainfall diminishes rapidly, and from May to September the climate is comparatively cool and dry.

LITTLE CRIPPLES CHRISTMAS HAMPER FUND.

To the Editor of THE LANCET.

SIR,—The King has again proved his kindly interest in the fund, founded by my father, for the annual distribution of hampers to crippled children and Guildhall entertainment to little Londoners, by heading the list for this the thirty-first year of the fund. Long experience has proved the absolute necessity of this fund which brings joy to many young hearts and strengthening encouragement to little children who are bravely struggling for health, often in straits of deepest poverty. The provision of joy to children is a cause which must surely stir every heart, and I venture to make an appeal for help which I trust will meet with an immediate response. All contributions sent to me at the address given below will be gratefully acknowledged by

Yours faithfully,

FLORENCE TRELOAR.

25, Ely-place, London, E.C. 1, Nov. 10th, 1924.

LEPROSY IN INDIA.

IN a recently published little book[1] Mr. Frank Oldrieve, Secretary to the British Empire Leprosy Relief Association, puts forward a plea for a common effort to get rid of leprosy in India, which, according to official statistics, affects more than 100,000 people, though there is reason to believe that the actual number is even larger. Mr. Oldrieve describes the misery of the victims of this disease and the social damage caused by leprosy. He also summarises the progress which has been made in dealing with the disease since Armauer Hansen discovered the *Bacillus lepræ* in 1874, and claims that a united effort on the part of the Government and the public would rid the great Indian Empire of this terrible disease in a very short time. Briefly the methods he advocates are an increase of voluntary institutions, larger facilities for segregation, special clinics for out-patient treatment in all large centres, the specia care of the children of out-patient lepers, and facilities for adequate treatment of every leper in the country. The book is a praiseworthy attempt to stimulate public interest in tropical diseases, the conquering of which is of vast importance to the well-being of the Empire.

THE "WHITE INDIANS" OF PANAMA.

IN the November issue of *Man* there is an interesting report by Dr. F. C. Shrubsall, Dr. A. C. Haddon, and Mr L. H. Dudley Buxton on the so-called white Indians of Panama. Three children, two boys and a girl, the parents of the girl, and two San Blas natives, were examined, and the conclusion arrived at was that the so-called white characters are due to albinism and are of no racial significance. The authors of the report state that the head form forehead, shape of face, nose, palpebral fissure, epicanthic fold, and general proportions of the body are clearly of local Darien type. The article is illustrated by reproductions of photographs, and the physical characteristics of the albinos are described in the text.

IN aid of Guy's Hospital, the Mayfair Dramatic Club will present the Maid of the Mill, an eighteenth century comic opera, on Monday, Nov. 24th, Tuesday, Nov. 25th, and Wednesday, Nov. 26th, at 8 P.M., at the Scala Theatre Charlotte-street, London, W.

THE

Lloyd Roberts Lecture

ON THE

RENAISSANCE OF MIDWIFERY.

Delivered under the Conjoint Scheme of the Royal College of Physicians, Medical Society of London, and Royal Society of Medicine, at the Medical Society of London, on Nov. 19th,

By HERBERT R. SPENCER, M.D., B.S. LOND., F.R.C.P.,

OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

WHILE thanking the Medical Society of London or nominating me to deliver the second Lloyd Roberts Lecture under the conjoint scheme, I regret hat I cannot claim the literary ability and charm which stamped the first lecture delivered by that disinguished man of letters, Mr. Edmund Gosse. Perhaps he Medical Society was influenced by the facts hat I enjoyed Lloyd Roberts's intimate friendship during the last twenty-five years of his life, that we were fellow workers in the same field of medicine, nd that the subjects, especially old books, which nterested him have a similar interest for me.

A PORTRAIT OF THE FOUNDER.

I have thought that I could best commemorate he founder of these lectures by giving a few particulars of his personality, character, and habits from my own xperience, and some particulars of the earliest books n midwifery in which he was especially interested nd of which he bequeathed to the Royal College of Physicians such an unexampled collection. Those books, published in the vernacular, were widely used for study by midwives, and may be said to have tarted the renaissance of midwifery.

Of Lloyd Roberts's personal appearance I need say but little: his portrait, painted by Sir William Orpen, now in the Arts Gallery at Manchester, and a replica by the artist in the Royal College of Physicians, will be acknowledged by all to be an admirable picture, and by all who knew him to be an excellent ikeness. I had the opportunity, just after it was painted, of comparing the portrait and the original ide by side.

Lloyd Roberts was short in stature, of stocky build, nd had the Celtic physiognomy and a Welsh accent much modified by his long residence in Lancashire. To the last he always addressed any man younger han himself as "lad." He was always neatly dressed, usually in a short black coat and dark trousers, and wore a silk hat tilted back on his head. He often wore a dark cape and a skull cap to protect him from he cold and draughts, of which he had an especial horror. Like his favourite author, Sir Thomas Browne, he thought it most important to keep warm. His clothes were made by the most renowned of ailors and, as he used to order a good supply in advance, he always appeared well dressed, even during he years of the war. In the hottest weather he would ide in a four-wheel cab with the windows closed. On his frequent visits to London he often used to ngage the same old cab-driver, and keep him waiting during his visits, and from the smiles upon the cabman's face I have no doubt he received a generous are. He was a very shrewd man and a great pracitioner, with a most impressive and kindly manner which procured him a host of patients. In his earlier days it is said he was somewhat aggressive; but in his later life he became, as Horace says old men hould, *mitior et melior*.

As an obstetrician and gynæcologist he practised nearly up to the day of his death over a period of more than 60 years, and his colleague, Dr. Archibald Donald, has pointed out the great amount of work he did at Manchester. He took up the operation of abdominal section early in his career. His first Cæsarean section, performed on June 3rd, 1867, figures as the first in the list of Dr. A. Routh's collection of cases of Cæsarean section by living British obstetricians which appeared in 1910. He published a work on the "Practice of Midwifery" in 1875, which reached a fourth edition in 1896 (an octavo volume of 558 pages). It was well written and well illustrated, and showed that the author kept himself abreast of the times. He read widely and was keenly interested in the work of younger men. At the same time he recognised that it was not everyone who was fitted to undertake some of the greater surgical procedures, such as the extended operations for cancer. He also did not practise the total operation in cases of myoma, although he recognised its superiority over the partial operation. In his work as an obstetrician and gynæcologist, which extended over such a long period of time, it cannot be said that he showed any great originality or made any noteworthy advance; but in the routine work of hospital practice he served for a period which is perhaps unequalled in the annals of gynæcology.

Although he was a connoisseur of good food and wine he was a small eater and a temperate drinker, and no doubt his good health and long life were in part due to his careful dieting; his lunch would have pleased Luigi Cornaro, for he told me it consisted for many years of a glass of milk. He had a cellar well stocked with wines of choice vintages, and was never happier than when dispensing them to his friends. When travelling he used to take his own wine with him, and would carry bottles wrapped in paper under his arm to the table at the hotel where he was dining. In a large public dining-hall his short figure in evening dress, wearing a black skull-cap and carrying two large bottles under his arms, would attract some attention, especially from the waiters; he always rewarded each of those who served him at the end of the meal. At the dinners to a small party of his friends he never gave any but the choicest wines, liqueurs, and cigars supplied from his own stock. Of pictures, prints, glass, china, and jewels (especially diamonds, which he had bought for his wife) he had a very valuable collection, acquired under the guidance of skilled experts, and by degrees he became an expert himself. In collecting old books he employed the most celebrated of the old-book sellers, and, as he had more regard to the condition and rarity of the book than to the price, he was able to accumulate a very valuable library, especially of old medical books, which to the number of 1800 (including 50 incunabula) he bequeathed to the Royal College of Physicians of London. This is said by the Harveian librarian, Dr. Arnold Chaplin, to be the greatest gift of medical books to the College since the Marquis of Dorchester's in 1680.

As regards medical practice and practitioners he was *laudator temporis acti* and spoke with great appreciation of the capabilities of some of the physicians whom he had known in his early days. He was lenient towards the foibles of some of his contemporaries, appreciated the work of younger colleagues, and was quick to take up a new idea. He always carried a note-book with him, in which he used to set down in his large scrawling script an idea or note of an old book or an edition which he did not possess, and to make sure there was no mistake he often got his informant to write the note.

In religious matters I think he was of the opinion of the philosopher who said that all men of sense were of the same religion, and when asked what that was replied: "No man of sense tells." He had many friends amongst church dignitaries and dedicated his 1898 edition of Browne's "Religio Medici"[1] to his friend the Marquess of Normanby, Canon of St. George's Chapel, Windsor. In his frequent week-end visits to London he usually attended the Sunday service at St. Paul's Cathedral or Westminster Abbey and sometimes the service at a Roman Catholic chapel. He had a great admiration for the English cathedrals, and, in spite of some apocryphal stories, I think he was a reverent man. He could hardly be otherwise than reverent who loved Sir Thomas Browne above all writers, who edited a charming edition of the "Religio Medici," who learned Italian in his old age that he might read Dante (on whose scientific work he wrote a book), and whose collections showed that he was a lover of the good and beautiful in men, ideas, and things.

---

[1] Lloyd Roberts possessed 21 editions of the "Religio Medici"; these are now in the Rylands Library, Manchester.

These brief particulars about my departed friend's personality I have thought it well to set down, mindful of the exhortation to commemorate our benefactors left us by Harvey, about whose personal characteristics we all regret that more particulars have not been transmitted to us by his contemporaries. It is for his medical library that he will be longest remembered, and especially for his unequalled collection of early medical books, including the "Byrth of Mankynde" (1540).

EARLY BOOKS ON MIDWIFERY.

It is the purpose of this lecture to give some particulars of the first books on midwifery in Germany, France, Italy, and England, which may be said to have started the Renaissance of Midwifery.

Obstetrics is an ancient art. It was outside the Garden of Eden that midwifery was born, "of man's first disobedience" with the dread decree to woman, "in sorrow thou shalt bring forth children." And we find the Garden of Eden incident referred to and depicted in some of the first books of midwifery (Fig. 1).

The early history of midwifery is too extensive to be treated here; but it may be stated that the most distinguished of the ancient writers on obstetrics was Soranus of Ephesus, who lived in Rome at the beginning of the second century of the Christian era under Trajan and Hadrian. He wrote περὶ γυναικείων παθῶν, which stands out as one of the most important works in the history of midwifery, which had at that time reached a high state of development.

Subsequently the art of midwifery made no advance at the hands of the Byzantines and actually declined amongst the Arabians, who devoted more attention to the destructive operations on the child than to conservative treatment of the mother. One factor in preventing advance in the science of obstetrics amongst the Arabians was the prohibition of anatomical research in the koran. But the chief reason why no advance was made was that the practice of midwifery was in the hands of midwives, as it had been since the earliest times.

The history of midwives is an interesting study in itself, too extensive to be treated here. Their virtues have been immortalised in the bible in the persons of Shiphrah and Puah, who refused to obey the command of Pharaoh to kill the male children of the Hebrew women. What a loss to the world it would have been if little Moses had been murdered by the midwives or had been allowed to perish in his ark of bullrushes amongst the flags! In Rome monuments still exist which were erected in honour of midwives in the days of the Empire, and though some of the midwives, like Terence's Lesbia and Mrs. Gamp, were inclined to have a liking for the bottle, as is suggested too in some of the oldest illustrations of the lying-in chamber, in the main they were an honoured class. Let us not forget that Socrates was the son of a midwife Phainarete, "a very noble and worthy midwife," to whom he owed the "ars obstetricia Socratis," painfully drawing forth ideas from his pupils as his mother had brought forth children from the womb.

Yet up to the time of the Renaissance no midwife had written a work which developed the science or advanced the art or dignity of her calling. For the well-known "Trotula" written in the thirteenth century is no exception. About the personality and even the existence of any such person as Trotula there is considerable doubt. In Spach's "Gynæcia" (1597) the work is said to be by "Eros quem aliqui Trotulam inepte nominant, medicus libertus Juliæ." In the same (as in the earlier 1566) edition of the Gynæcia, the masculine adjective *compulsus* employed in the preface shows, unless the MS. was erroneous or miscopied, that the author was a man. It was probably written by a Salernitan male physician. The work is noteworthy for describing (as Soranus was the first to do) the support of the perineum and the repair of complete tear of the perineum, which appears in "Trotula" for the first time in the history of midwifery.

There is in the British Museum (Sloane 2463) a Trotula MS. of the fourteenth century (for the typed transcript of which I am indebted to my friend Dr. Charles Singer) in which the operation is described: "Other whiles sume women have so gret greva(n)ce in beryng of a childe that þe skynne þat is between the two prevy membres brekith a two and all is a hole." After applying butter and wine and replacing the womb which is to be made *nesshe* with wine "a good whiles" you are to "sowe to geder þat pece that is broken with a silken threde with a quarell-nedell [2] in thre places or in foure and sithen do pitche on a softe lynnen cloth and leye it to þe prevy membre."... "and let her liggen as I sayd rather a sevyne dayes or a nyne and let her eten and drynken in þat while but litell and keep hem well from cold and fro metes and drynkes that myght maken her eny coughe. And for to kepe women from this myschef in þat time that they traveyllen of child let make a rounde thyng of þe shappe of an eye of small lynnen clothe and pitch it on her fundeme(n)t and everich tyme of chylde and ev(er)yche tyme let thrust þat balle in her fundement and þ(at) shal saven þe skyn hole from brekyng."

The expression "thrust that balle in her fundement" does not give the true sense of the original. In Spach's Gynæcia, 1597, the description is: "Præparetur pannus in modum pilæ oblongatæ, et ponatur in ano, ad hoc ut in quolibet conatu ejiciendi puerum, illud firmiter ano imprimatur ne fiat hujusmodi continuitatis solutio." It is clear, therefore, that Trotula, following Soranus, recommended the pressure of the pad *against* and not *in* the anus.

Until the invention of printing the wisdom of the ancients was inscribed in such manuscripts comparatively few in number, usually written in the classical language and therefore readable only by the learned. For the preservation of these works we are indebted in great part to the various religious bodies and especially to the monks. The Church of Rome, which has at times opposed the pursuit of medical knowledge, has also been one of its greatest promoters. Many examples of this are given in Curatulo's "L'Arte d Juno Lucina in Roma." And there are not a few instances of ecclesiastical dignitaries who have been practitioners of medicine. Pope John XXI., the only member of the profession to occupy the papal chair, was a doctor who taught medicine in Siena in the middle of the thirteenth century. As Petrus Hispanus he published his work "Thesaurus Pauperum," which was printed for the first time in 1476; in the Lloyd Roberts Collection at the Royal College of Physicians are three copies of the work, including one of the 149 edition.

Nicholas de Fernham, an Englishman, was professor of medicine at Bologna, whence he returned to England in 1241 and became bishop of Durham. In a fourteenth century MS.[3] we read:

> "This medecyne (elecampane) taught þe Pryor o Bermondsey to a woman þ(at) was nygh dede on the flux of hy(re)marice. And to Amende hyrre stomak he let take two handfuls of þe medell rynde of þe brome & let sethe hyt in thre potell of clere water to a potell clens hit & putt þer to half a pint of whyt suger and lete seth eftsones [4] & gef hyr to drynke."

The Church of England, like the Church of Rome has had its medical chief. In view of the former practice of the Archbishop of Canterbury of licensing doctors and midwives, it is interesting to note that the only Primate who belonged to the medical profession was Archbishop Secker (*ob.* 1768).

---

[4] Soon after, quickly.

The Renaissance of midwifery occurred somewhat ater than that of other branches of learning. The ntellectual world was in labour, in the throes of delivery from the domination of the Church, from the blind acceptance of the authority of the ancient writers Aristotle and Galen, and from the restrictions of the classical languages. The Reformation had brought about the first stage: Paracelsus did something to bring about the second stage when he cast the works of Galen into a bonfire in the streets of Berne and anathematised his opponents with the words “sic vos ardebitis in Gehenna.” And Eucharius Rösslin seized the opportunity afforded by the discovery of printing to publish his “Rosengarten” in German, so that it could be understood by the people and particularly by the midwives for whom it was written.

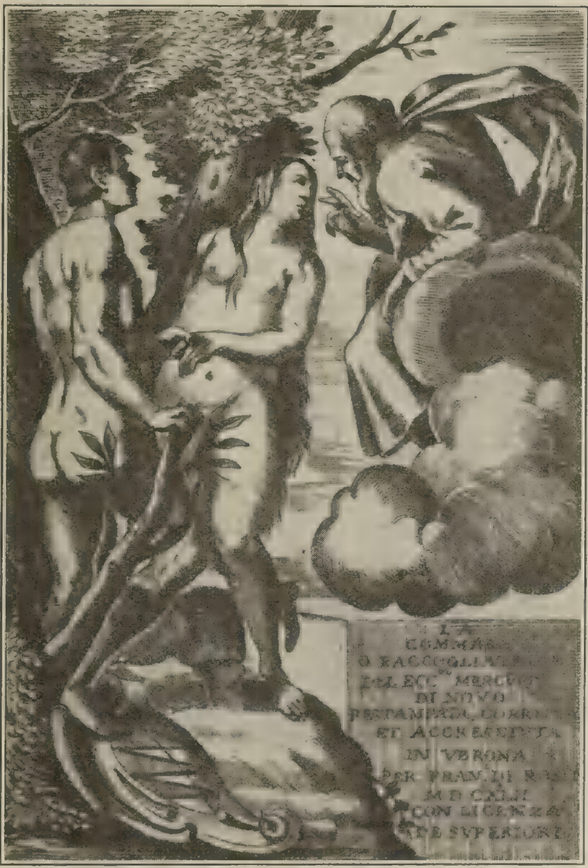

FIG. 1.—Title-page of the 1642 edition of “La Commare,” showing the Lord God addressing Adam and Eve in the Garden of Eden. From a copy in the author's library.

Although Ortolff von Bayerland had published, about the year 1495, at Ulm a German work showing “how women should conduct themselves before, during, and after childbirth,” it did not contain much detailed account of obstetrics. To Eucharius Rösslin is due the honour of the first printed work specially written for midwives.

RÖSSLIN'S “ROSENGARTEN” (A.D. 1513).

Eucharius Rösslin Röslin or Rhodion[5]) was a physician at Worms and afterwards at Frankfort on the Main. According to documents still existing at Freiburg in Breisgau, Rösslin was an apothecary there in 1493 and 1498. In 1502 he was received into the Citizen's Union or Guild Bürgerverband) and was a householder in 1526. In 1504 a legal action was brought against him for “misshandlung,” as the result of which a verdict was given against him and he was compelled to pay all costs and a fine of 3½ pounds of pfennigs. An autograph letter from Rösslin referring to this action has been published by K. Baas and reproduced by G. Klein in the notes to his reprint of the “Rosengarten” (1910). In 1506 he was elected physician to the city of Frankfort for a period of six years at a yearly stipend of 60 florins; and in 1508 he entered the service of the Duchess of Brunswick and Lüneberg to whom he dedicated his “Rosengarten.” Before the expiry of his term of office he left (in 1511) the service of Frankfort and became city physician to the town of Worms, returning again to his Frankfort post at an increased salary of 70 florins. According to Baas, he died in September, 1526.

v. Siebold in his Geschichte der Geburtshülfe 1845) makes a curious error in giving the date of his death as 1553 or 1554, confusing this Eucharius Rösslin with his son who bore the same name and died in 1553 or 1554. The error is the more remarkable because in the Latin translation of the “Rosengarten,” entitled “De partu hominis,” there is a preface dated 1532, written by Christian Egenolph and addressed to Eucharius Rhodion which refers to the death of the father “cui bene sit in Domino, cujus in hac urbe tu et nomen refers et functionem.” In this work Rösslin acknowledges his indebtedness to the ancient writers Hippocrates, Galen, Rhases, Averroes, Avicenna, and Albertus magnus; but the most important parts are taken from Soranus, probably from a manuscript by Moschion (or Mustio), which itself was copied from Soranus “word for word.”[6] For the discovery of the first manuscript of Moschion we are indebted to the learned writer on medicine and natural history, Conrad Gesner. It is suggested by Gustav Klein that Rösslin used the Codex Palatinus Latinus which was at that time in Heidelberg, not far from Freiburg, Worms, and Frankfort, where Rösslin lived.

Some of these manuscripts, dating from the ninth to the fifteenth century, were illustrated, amongst the most interesting being the plates of the fœtus in utero which, reproduced in the English translation, “The Byrth of Mankynde” (1540), were amongst the earliest copperplates published in this country. The figures have been often reproduced. Dr. Klein has published a photographic reproduction of them from the Munich Codex Latinus of the thirteenth or fourteenth century. One plate, not met with in the earliest MSS., shows twins grasping each other by the heel: this was probably drawn by a monk in reference to the birth of Jacob and Esau.

Rösslin also published some admirable original plates—viz., the dedication plate, depicting the author presenting his work to the Duchess of Brunswick and Lüneberg, a plate showing the midwife examining a parturient woman (Fig. 3) and a figure of the birth-chair. It is stated by G. Klein that about 100 editions of “Rosengarten” are known, three editions being published in 1513 (Figs. 2 and 3). He gives a reproduction of the title-page of the 1513 edition printed by Gran at Hagenau, which shows a mother with her naked boy and a midwife holding a babe wrapped in swaddling clothes. The title-page of the 1524 edition is also given by G. Klein (Fig. 4). It is a fine representation of the lying-in chamber showing the midwife bathing the baby. In this plate the midwife sits with her bare legs in the tub, no doubt to make sure that the water was of a proper temperature, a useful practice adopted also by the Japanese midwives (Fig. 5).

---

[5] The name Rösslin was latinised into Rhodion in the Latin ranslation issued by Eucharius Rösslin the younger in 1532.

[6] As stated in the Codex Hafniensis: Ingerslev, Jour. of Obs. and Gyn. of Brit. Empire, 1909.

Under the title "De partu hominis," Rösslin's son published a Latin translation, of which, according to Klein, 11 or 12 editions appeared, the first in 1532. The title-page of my copy of the 1554 edition of "De partu hominis" gives the representation of the lying-in chamber reversed from that in the "Rosengarten" 1524 edition, and some quaint woodcuts, depicting the feeding and rearing of the child. The "Rosengarten" was translated into English by Jonas under the title "The Byrth of Mankynde" and published for the first time in 1540. A second amended English translation was made by T. Raynalde, who used the Latin edition of E. Rhodion, the younger. The late Dr. J. W. Ballantyne wrote a very full account of the English work, giving illustrations from many of the editions. He had not had an opportunity of inspecting the first edition, which is very rare, the only three copies he had been able to find in existence being in the libraries of Prof. Klein, of Munich, and the British Museum. The Royal College of Physicians now possesses 15 copies (11 editions) of "The Byrth of Mankynde," of which 11 copies, including two of the rare first edition, came from the Lloyd Roberts Collection. The celebrated plates of the position of the fœtus appear in this edition and not "for the first time in the 1560 edition," as once stated by Dr. Ballantyne.

The "Rosengarten" contained little that was original; but it had the merit of being written in the vernacular in which it could be read by midwives, in whose hands the practice of midwifery almost entirely lay; it was the first work dealing with obstetrics apart from medicine and surgery and in its illustrations it gave for the first time printed figures of the birth-chair, the lying-in chamber, the position of the fœtus in utero, and of the feeding and rearing of the child. Some of the plates are of high artistic merit and were copied by subsequent writers, including Rueff and Ambroise Paré.

FIG. 2.—Title-page of one of the 1513 editions of the "Rosengarten." From a copy in the library of the Royal Society of Medicine.

AMBROISE PARÉ'S "LA MANIERE DE EXTRAIRE LES ENFANS" (A.D. 1551[7]), "DE LA GENERATION DE L'HOMME" (A.D. 1573).

The first of the obstetric treatises by Ambroise Paré entitled "La maniere de extraire les Enfans tant mors que vivans hors le ventre de la mère, lors que nature de soy ne peult venir a son effect" appeared at the end of the "Briesve collection anatomique," published in 1551. The second treatise, "De la Generation de l'Homme receuilli des anciens et modernes" was published as an octavo volume in 1573 under the title "Deux livres de chirurgie" and was reproduced in 1575 in the first edition of the complete works of Paré. In his "Maniere de extraire les Enfans" Paré revived the operation of podalic version which had been entirely neglected for many centuries. The operation had been practised in the time of Celsus, Soranus, and Philumenos, but had found no place in the treatises of the Arabian physicians. Paré himself does not claim originality; but acknowledges that he had seen podalic version practised by Thierry de Hery and Nicole Lambert, "master barbers and surgeons in this town of Paris."

Paré's description of the operation is as follows:—

> "And supposing that the child presents naturally having the head towards the outlet (au coronement), to duly deliver it by art you must gently push it back in the contrary direction and seek the feet and draw them into the outlet. By doing this you will easily turn the child. And then when you have drawn the feet into the outlet you must draw one outside and tie i above the heel in the manne of a running noose with a moderately long fillet like tha with which women bind thei hair. Then you will replac the said foot into the sai womb and having found th (foot) you will draw it outsid and then will pull on the fille to which the other foot i attached. And when you hav thus drawn the feet outsid the womb you will draw o both, equally on one side a on the other, little by littl and without violence if yo possibly can."

He also advises tha the abdomen should b moderately bound an pressed above the umbilicus and the mothe should be commanded t hold her breath at inte vals by closing her nos and mouth, and that sh should bear down as muc as possible. Sternutatori may be given to aid in th expulsion of the child. H warns against pulling o the arm in case of presentation of the shoulder, fo which he recommended, i certain neglected case amputation of the lim followed by podalic ve sion. Paré's re-introdu tion of podalic versio after many centuries neglect marks him as the master-writer of th Obstetric Renaissance. His work was plagiarise by Franco[8] in 1561, and attempts have been mad in modern times to deprive Paré of credit by quotin from certain editions of his work.

Paré's works passed through many editions, and was his practice to make alterations when additio to his knowledge called for them. Of his views the separation of the bones of the pelvis in the a of childbirth, which have been criticised, he write "mais véritablement les os de hanches et pu s'ouvrent et separent les uns des autres."

> "I had hitherto maintained," he continues, "by wo and writing that the os pubis could not separate and par open in the act of childbirth; however, the contra appeared to me on the first day of February 1579 by t anatomy of a woman who had been hanged fifteen da after being delivered, of whom I saw the dissection a found the os pubis separated in its middle about half finger's breadth in the presence of Master Claude Rebo and other sworn surgeons at Paris. Also we saw the ischion separated from the os sacrum. If anyone is willing to believe it I will refer him to the book of Nat which does things which our intelligence is not capable understanding."

Paré repeats the Hippocratic opinion that in t ase of children born at the eighth month “their ife is brief or null.” He recommends late ligature f the cord if the child is feeble. The cord should be ied at a distance of three fingers' breadths from the mbilicus, and after the first knot is tied the ends of he ligature should be returned and two knots made n the side opposite to the first knot and tied more ightly than the first. And then “it only remains o leave the child to God and the women.”

---

[7] Malgaigne: "Œuvres complètes d'Ambroise Paré," 1840. Eloy gives the date of publication as 1549; Fasbender 1550; the "Privilegium" is dated July 6th, 1549.

[8] Traité des hernies, Lyon, 1561.

The work on the “Generation of Man” contains he anatomical and other figures, including the birth-hair, copied from Rösslin and Rueff. Paré published figure of lead caps for lcerated nipples which are till employed at the resent day. I have in ny library a work by T. unus,[9] with an autograph inscription by the uthor to Conrad Gesner, hich recommends the pplication of wax cups or himbles containing a few rops of pine resin to the ipples, to be worn during he last three months of regnancy as a certain eans of preventing racks. To the criticism hat some women or their usbands might object to he smell of the resin, unus replies that anyone ho had suffered from the *agnum malum*, cracked ipples, would tolerate the mearing not only of the ipples but of the whole reasts with medicines owever odoriferous. hese are examples of hich there are many howing that prematernity are is not a modern invention but was practised by he Renaissance writers nd also by Ortolf von ayerland, who gives etails of measures to be aken “vor der Geburt.”

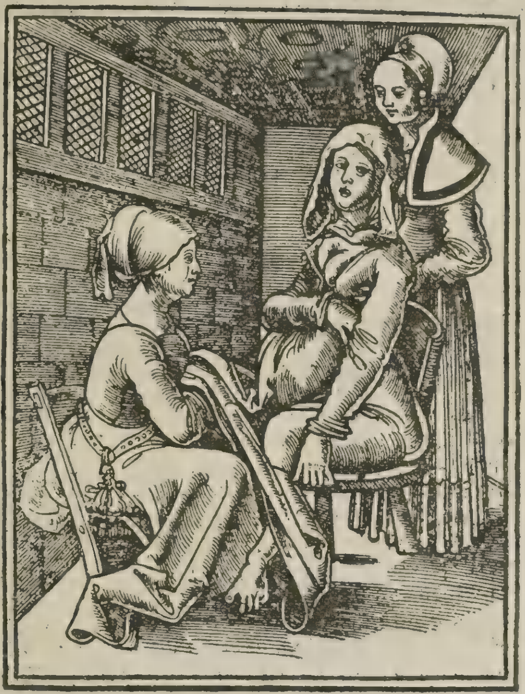

FIG. 3.—Showing midwife examining patient seated in the birth chair. From the copy of the 1513 edition of the “Rosengarten” in the library of the Royal Society of Medicine.

The movements of the hild felt on palpation were irst described by Paré. He enied the existence of the ymen except as a rare ccurrence. He published number of figures of intruments for the delivery f the dead child and gave an illustration of the peculum matricis, an ancient instrument known to he Romans, also of instruments for the fumigation f the uterus. Of Cæsarean section on the living he ad seen disastrous results at the hands of Guillemeau hich caused him to write, “Je ne conseillerai amais de faire tel œuvre ou il y a si grand peril sans ul espoir.” It was in reply to this statement that is friend Rousset wrote the first work on Cæsarean ection, “Hysterotomotokie” (1581).

The literature of the life and works of Paré is very xtensive. As was the case with the founder of this ecture, there seems to be a doubt about the actual ate of Paré's birth, the years 1509, 1510, 1514, 1516, 517, 1528 having been given by various authors. Malgaigne[10] states, on the authority of Bégin, that A. Paré was actually born in 1517.” He would hus be 73 and not 80, as usually stated, at the date f his death.

On St. Bartholomew's Day, 1572, “it was not easonable that he should be massacred,” King Charles IX. exclaimed after taking a shot with his arquebus at his less distinguished subjects, “il pouvait servir à tout un petit monde.” This service Paré, the Reformer of Surgery, the Reformer of Midwifery, continued to render up to the time of his death in 1590—and “his soul is marching on.”

SCIPIONE MERCURIO'S “LA COMARE” (A.D. 1596).

The first of the Italian writers for midwives was Scipione Mercurio, who published his work entitled “La Comare o Riccoglitrice” in 1596.

Scipione Mercurio was born in Rome about the year 1540 and studied medicine at Bologna and Padua, but soon devoted himself to theological studies and entered the Dominican monastery at Milan, where he took the name of Hieronymus. He still continued to occupy himself with the study of medicine, and finding his monastic life did not afford him sufficient opportunities for the practice of medicine he quitted the monastery and travelled in France and Spain in the years 1571 and 1572 as physician to a German officer, Hieronymus de Ladrone. On completing this journey he returned to Italy and practised with great success in Padua and Milan. He had studied in Bologna under the celebrated Arantius, of whom he speaks in the highest terms as “the most learned anatomist of his time and my very kind preceptor.” He mentions a case in which he saw Arantius, in the year 1578, deliver a living child by Cæsarean section from a woman who had been killed in the ninth month of pregnancy. He states that Arantius had familiarised himself with the anatomical conditions of pregnancy by performing many dissections of gravid women. He had also seen Arantius demonstrate the hymen, the existence of which, except as a rarity, had been denied by Paré.

Scipione Mercurio states that in Toulouse he had seen two women who had been safely delivered by Cæsarean section which at that time (1571) was “as well known in France as bleeding for headache in Italy.” He may be said to have introduced the operation of Cæsarean section on the living woman into Italy and published the first printed illustration of the operation.

Scipione Mercurio led a stormy and adventurous life; at one time travelling with a German officer, Ladrone, in France and Spain, at another pursuing his theological studies, then abandoning these for the practice of medicine, and again resuming them; finally settling in Venice where he lived for 15 years. He died about the year 1615 or 1616, according to Ghilini in Venice, according to Renazzi in Rome in the ancient Dominican convent of Santa Maria. His other writings show his great interest in medicine, and he seems to have specialised in the practice of obstetrics. He had little faith in medical writers who lacked practical experience. Of Sansovino's “L'Edificio del corpo umano,” he writes that the author was neither a physician nor a surgeon, and "what," he asks, "could he say of value about a profession which he did not know or practice ?" Of Jacob Rueff, whose belief in astrology he condemns, he complains that he was a "mere surgeon," and relied for many of his statements on the authority of others. Mercurio's object was to write a work for the midwife in a language which she could read. "Some Roman Aristarchus" might object that he had not written it in pure Tuscan. "No," replied he, "I have written it in the Roman dialect because I am a Roman." Those who affected the Tuscan style he referred to Boccaccio and Bembo. If they did not like his work, let them do him the great favour of not reading it. Perhaps the less it pleased his critics the more it would please others. He acknowledged that he had profited by the works of others—he gives a list of 80 authors whom he had consulted—and says he could never pardon Aristotle for adopting the statements of Hippocrates without once mentioning his name. Any errors in the work he prays The Lord will enable him to see and amend and begs his critics not to censure that which is written for a good purpose.

[9] Thaddeus Dunus: “Muliebrium morborum remedia,” 565.

[10] Malgaigne: Loc. cit.

Mercurio's writings show that he was a man of wide erudition which he was wont to bring to bear upon his critics in pointed shafts of wit and learning. His evident fondness for polemics explains the chequered character of his career. Yet withal Mercurio has a charitable spirit and a kind heart, as is shown in many places in "La Comare," and especially in a chapter on the suckling and home-nursing of children by their mothers. An eloquent passage on the joy of a father in greeting his children after his day's work is over leads one, in the words of Curatulo, "to make strange conjectures about this Dominican friar, whose life would furnish the material for a most interesting psychological romance."

men Roſengarte.

FIG. 4.—Title-page of the 1524 edition of the "Rosengarten." From G. Klein's reprint of the 1513 edition, showing the midwife bathing the infant while sitting with her bare legs in the bath.

"La Comare" is the first work in which contraction of the pelvis is mentioned as an indication for Cæsarean section. It contains a description and illustration of the "hanging-legs" position for delivery in cases of contracted pelvis, which Walcher published in 1889 as something new, and of the position in which very fat women should be placed for delivery, a position which Osiander says even practised acrobats could hardly maintain for more than a quarter of an hour. There is also a description of the operation of bimanual version which is usually associated with the name of Braxton Hicks. Mercurio advised that the diet of pregnant women should be reduced one-third during the last three months.

The work is divided into three books. The first book deals with natural labour and the care of the pregnant woman and of the new-born child by the midwife. The second book deals with præternatural labour—i.e., with the child's hands, feet, or side presenting—and shows how the midwife should deal with these "difficult and dangerous cases." The third book deals with the maladies which may occur to the lying-in woman and new-born child, and teaches the midwife how to treat these maladies in case the patients do not wish, or are ashamed to call in a doctor.

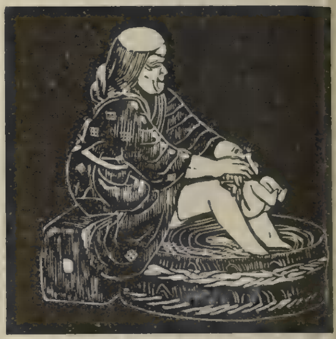

FIG. 5.—White-line wood engraving by Horace Gerrard (from an antique Japanese ivory netsuke in the author's possession) showing the midwife as in Fig. 4.

Von Siebold in his "Geſchichte der Geburtshülfe" (1845) says "La Comare" was first published at the beginning of the seventeenth century—Haller gives the date of the first edition (which he had not seen) as 1604. Quetif and Eckard, the biographers of Mercurio, speak of an edition which appeared before 1600, but leave the matter doubtful.

The first edition actually was published in 1596, the second and third books being dated 1595. That "La Comare" is a *cinque cento* book was first made known by Davidson,[11] of Breslau, in 1864. A few years ago I was fortunate enough to obtain a copy of this edition, which is very rare, only three other copies being known to exist. Fasbender says there were 17 editions of the work, and Curatulo[12] gives a short account of these 17 editions. I possess two editions (1680 and 1786) not mentioned by Curatulo, and these with the 1713 edition in the Lloyd Roberts Collection of the Royal College of Physicians, bring the number of the editions of "La Comare" up to 20.

The first edition* "La Comare o Ricoglitrice," Venice, G. B. Ciotti, 1596 (second and third book dated 1595), 4°, is very rare. There is a copy in the Marcian Library at Venice, another in the Library of the Arcispedale in Florence, a third in the Alexandrine Library at Rome, and a fourth copy is in my possession. There are some good anatomica figures from copper plates by Franciscus Vallegius The other figures are rough woodcuts. I have given a reproduction of the title-page and some other figures from this edition in the Harveian Oration (1921) The second edition,* "La Commare o Riccoglitrice," Venice, 1601, G. B. Ciotti, is also rare. The second book has no separate title-page. The third book is dated 1600. There is a remarkable title-page (Fig. 6) to this edition which is dedicated to Octavian Malipiero, the stemma of whose family is given below, and above is a portrait of Catherine Maripiero who fell while engaged in sinking the Turkish fleet at the battle of Lepanto (1571), in which Cervantes was wounded and lost the use of his left hand. At the sides of the title-page are figures o cipio Africanus ("belli gloria") and Cato of Utica 'reipublicæ splendor"). The artist is not named, ut a comparison with his other work shows that the late was engraved by Vallegius.

---

[11] Monatschrift f. Geb. u. Frauenkr., Bd. xxiii., p. 345.

[12] Curatulo: Loc. cit.

* A copy is in my library.

The third edition appeared in 1606 (title-page as in econd edition, dated G. B. Ciotti, 1601). In his edication (of the first book) to Octavian Malipiero, e author signs himself Girolamo Mercurio Romano from the con- ent of S. ustorgius at ilan, 30th Octo- er, 1604," and ates that this the third lition, "ristam- ata la terza olta" ("re- rinted for the ird time"), hich really eans *printed* for e third time, r he adds that dedicates it Malipiero with e same affec- on as he did e second im- ression (la conda impres- one). The cond book has otti's "Min- va" printer's late, and is ted 1606. The ird book has nilar title-page d date (1606) the second. is edition is metimes called e 1604 edition e.g., by Cura- lo,[13] and was ought by aller to be the st edition. The le-page is that the second lition, and, though the dication is ted 1604, the tes on the title- ges of the cond and third oks show that did not appear 1606.

Subsequent itions accord- to Curatulo peared in 1607, 12, 1614, 18,* 1620, 21,* 1642,* 45, 1652,* 1653, 1662, 1671, 1676, and 1703.* Of se editions those marked with an asterisk are in library; the 1612 edition quoted from v. Siebold Curatulo,[14] I have been unable to find in the refer- ce given, and the 1614 edition, quoted from Haeser, given by v. Siebold as *1613*.

I possess two other editions of which I have not nd a record—viz., the 1680* edition, Venetia—affano Curti, and the 1686* edition, Venetia—F. Valvasense. [It is possible that the 1676 edition, quoted by Curatulo from Quetif and Eckard, also printed by Valvasense, has been mistaken for the 1686 edition.]

Lastly, the Royal College of Physicians has a copy of the 1713 edition, Venezia, Dominico Lovisa, in the Lloyd Roberts collection. The 1642* edition has a fine title-page of the Lord addressing Adam and Eve in the Garden of Eden (Fig. 1). Appendices on "Il Colostro" by di Castro and on Baptism by "Un gravissimo autore" are added to this and later editions. An additional appendix from Marinello's "Medicine partinenti al Infermità delle donne gravide" appears in the 1703 and 1713 editions.

Besides "La Comare" Scipione Mercurio wrote "The Catholic Courtier"—"The French Disease"—"Comments on Tasso's Seven Days of the Creation of the World"—"The Clock of Health"—"On the First Part of the Aphorisms of Hippocrates"—"On the Popular Errors of Italy."

FIG. 6.—Title-page of the second edition of "La Commare," formerly thought to be the first edition. This title-page, unaltered, was used for the third edition, and, with the date altered to 1621, for the 1620 and 1621 editions. The title-page of the first edition (1596) was reproduced in the Harveian Oration for 1921.

WILLIAM HARVEY'S "DE GENERATIONE ANIMALIUM" (A.D. 1651).

The Renaissance of Midwifery occurred later in England than in Germany, France, and Italy. It had made some progress as a result of the appearance of translations of the works of Rhodion and Paré; but no original book on the subject had been published until 1651, when Harvey published his "De Generatione Animalium" with the chapter "De Partu" which justifies Aveling's designation of Harvey as the Father of British Midwifery. I have elsewhere[15] given a detailed account of Harvey's contributions to embryology and midwifery and have pointed out the teachers at Padua who had specially written on those subjects. Spach's third edition of the Gynæcia, a collection of ancient and recent writers on gynæcology, had appeared in 1597, and the first edition of Scipione Mercurio's work, "La Comare," had been published in 1596, four years before Harvey went to Padua to study.[16] Scipione Mercurio had himself practised obstetrics at Padua and it was probably the great attention devoted there to obstetrics and the appearance of "La Comare," the second edition of which was being prepared when Harvey joined the University, which stimulated Harvey to emulate the Paduan obstetrician by writing his "De Partu," which was the first original English work on midwifery.

---

[13] Loc. cit.

[14] Loc. cit.

* A copy is in my library.

[15] Harveian Oration, 1921: William Harvey, Obstetric Physician and Gynæcologist.

The "De Generatione Animalium"—for the publication of which we are indebted to Sir George Ent—consists of 72 "exercitations" followed by chapters on "labour," "the membranes and humours of the uterus," and "the conception." There is a printer's error in the numbering of the exercitations of the first (Latin) edition, printed in London, Exercitatio V. being printed Exercitatio IV., and the error is continued in the subsequent "exercitations," so that the last appears as Exercitatio LXXI., though it should be Exercitatio LXXII. This printer's error, which was corrected in the later editions, may have led to some mistakes in references to Harvey's work.

The first (Latin) edition, printed in London 1651, contains a striking title-page representing Job sitting on a throne and opening an egg from which various animals are escaping; on the egg is printed "ex ovo omnia," a pregnant generalisation which Harvey made as a result of his researches on generation. The legend is omitted from the egg in the first Amsterdam edition (Leers, 1651). The first English edition appeared in 1653 with a portrait by Faithorne, which is often missing. It is one of the best of the engraved portraits of Harvey."

Prefixed to the first English edition is a laudatory ode to "the incomparable Harvey," signed M. LL., M.D., which stands for Martin Llewellyn, M.D. The English edition is written in quaint and spirited language and was probably produced under the supervision and with the approval of Harvey, who lived for four years after its appearance. Dr. Robert Willis, in the preface to his translation of Harvey's works, says that the English translation of the 1653 edition was made by Martin Llewellyn, but does not give his reasons for the statement, which perhaps receives some support from the facts that Harvey handed over the Latin edition to Ent to see it through to the press, that Llewellyn certainly wrote the ode to Harvey, was, like him, a Royalist and obtained the M.D. Oxon, and was a candidate for the R.C.P. in the year (1653) in which the translation appeared.[18]

Harvey's friend and patient, Francis Bacon, published in 1605 his "Advancement of Learning" which contains his inductive method—the accumulation and systematic analysis of facts obtained by observation and experiment—which forms the basis of modern scientific work. Harvey alludes to Bacon as "our most learned Verulamius," and we require stronger authority than Aubrey's for the statement that Harvey spoke derisively of him. Indeed, the preface to the "Generation of Animals" in its arguments and often in its language recalls Bacon's "Advancement of Learning," in which the "diseases and errors of learning" are described. Harvey also appealed to observation and experiment. "We must not," says he, "rely upon other men's experience, but on our own." "Every perfect science builds upon these principles which it finds out by sense," but "we must have a special care that we be sure those principles are safely grounded." "For want of this," he says, "we have many sophisters and book-wrights, but few wise men and philosophers."

The great and original merit of Harvey's work on generation lies in the careful and methodical observation and record of the embryo and fœtus at all stages. Harvey did for development what the illustrious Paduan Professor Morgagni subsequently did for disease in his "De sedibus et causis morborum" (1761). The chapter on labour (De Partu) deals with the subject from a scientific and practical point of view. The scientific part consists in criticism of previous opinions in the anatomy and physiology of the fœtus and of parturition based on his own observations. The practical part gives evidence of extensive personal experience in midwifery and is in the main devoted to the recommendation of patient watchfulness and gentleness, imitating Nature in ordinary cases and podalic version in difficult ones.

England was not only the last of the great countries to produce a writer on midwifery, but was equally tardy in the recognition and regulation of its practitioners. In 1616, the year in which Harvey was propounding his immortal discovery of the circulation of the blood, Peter Chamberlen ii. made a petition to King James that some order might be settled by the State for the instruction and civil government of midwives; but nearly 300 years were to elapse before the desirable result was obtained, in the Midwives Act (1902), through the persistent efforts of the Obstetrical Society of London. Harvey inveighs against the meddlesome officiousness of the midwives Another distinguished obstetrician, his friend Percival Willughby, writes more fully of their shortcomings and misdeeds, and testifies to the value of Harvey's teaching in the following words: "I know none bu Harvey's directions and method, the which I wish al midwives to observe and follow and oft to read ove and over again; and in so doing they will bette observe, understand and remember the sayings and doings of that most worthy, good and learned docto whose memory ought to be had for ever in grea esteem with midwives and child-bearing women."

The first books of the Obstetric Renaissance in Germany, France, Italy and England achieved thei object of being widely read by midwives, as we learn from the history of Louise Bourgeois and Justin Siegemundin. The book introduced them to th wisdom of the ancient writers, and in the cases of Pa and Mercurio to methods of treatment which had bee long neglected and forgotten. England was fortunat in having as the father of English midwifery, Harvey who introduced into that branch of medicine the wid view, the scientific spirit, and the conservative practic which have been its characteristics. It was Harvey' inculcation of patience and gentleness in imitation o Nature, adopted by Smellie and Hunter, which mad such a strong impression on Boër, the founder of th great Viennese School of Midwifery, who, after studying in France and England, adopted the Britis practice "having learnt in France what Art, i England what Nature, could do."

The purely British operation of induction of pre mature labour for cases of contracted pelvis can b attributed to the same conservative spirit. And if w add the discovery of the fœtal circulation by Harvey of the forceps by Chamberlen, of chloroform b Simpson, and of the antiseptic system by Lister, or may claim for British medicine that, though it wa last in producing a writer on obstetrics, it has not bee least in conferring benefits on parturient women.

THE LATE DR. R. R. HARPER.—Robert Russe Harper, L.R.C.P. Lond., L.S.A., who died at his residen at Westgate-on-Sea, Kent, in his seventy-first year, was a old student of St. Thomas's Hospital Medical School ar qualified in 1875. On qualifying he joined his father practice at Holbeach, Lincolnshire, where he led an acti professional life for many years. On the outbreak of th late war he offered his services to the War Office and w subsequently attached to the No. 1 Birmingham W Hospital, where he worked till ill-health compelled him resign. After recuperating his health he was appoint resident medical officer of the Pensions Hospital, Birmingha and on retiring from that position spent some time in tra in England and in 1920 settled down at Westgate-on-S Early this year he underwent an operation from which never really recovered, and he died peacefully in his slee He played Rugby in his early days for his school and w instrumental in organising the first Inter-Hospitals C Competition. Dr. Harper leaves a widow and two sons.

SPONTANEOUS SPLENIC RUPTURE IN MALARIAL TREATMENT.

BY G. DE M. RUDOLF, M.R.C.S. ENG., D.P.H.,
ASSISTANT MEDICAL OFFICER IN CHARGE OF LABORATORY, CLAYBURY MENTAL HOSPITAL; CLINICAL ASSISTANT, NEUROLOGICAL DEPARTMENT, KING'S COLLEGE HOSPITAL.

IN a recent number of THE LANCET [1] appears an annotation describing the occurrence of spontaneous rupture of the spleen in artificially induced malaria in a general paralytic. The case, which was recorded by Alexander in *Le Scalpel*,[2] underwent with apparent impunity eight rigors but then collapsed suddenly on his bed. He was found to be dead. At the autopsy it was found that the spleen, which was soft, had ruptured.

With the object of endeavouring to determine whether spontaneous rupture of the spleen would with any frequency be likely to occur in enfeebled general paralytics, or whether it will be sufficiently rare to remain merely a clinical curiosity in the history of malarial treatment, some observations, described in this paper, have been made. In naturally acquired malaria rupture of the spleen may be due to trauma, for instance, a blow or an exploratory puncture (Osler),[3] or it may be spontaneous. The organ is enlarged and, in acute cases, soft, and presumably spontaneous rupture is due to the organ having increased in size to such an extent that any extra strain causes the rupture to occur. This extra strain might be due to pressure upon one part of the structure causing an increased tension in the remainder, or possibly to the rhythmical contractions which occur about once a minute in the organ (Halliburton).[4] Now if the spleen of the general paralytic is large before the inoculation with malaria it would be expected that there would be an appreciable risk of rupture during the rigors when the spleen enlarges. If, in addition, the organ were soft the risk might be serious, for a soft organ would be more likely to rupture than would a firmer structure.

The Spleen in the General Paralytic.

In order, therefore, to endeavour to determine whether the spleen of a general paralytic is more likely to rupture during malarial rigors than is the spleen of a normal person, it is necessary to know whether the organ is enlarged and soft in the paralytic. The weight of the spleen in health is given as being from 142 to 198 g. by Sims Woodhead,[5] as being from 150 to 200 g. by Hewlett,[6] and as about 200 g. by Howden.[7] The weight of the spleen in general paralysis, however, tends to be below these figures, as is shown by the following table, constructed from the post-mortem accounts of 50 general paralytics who have died during the last two and a half years at Claybury Mental Hospital, both males and females being included.

Weight in grammes.	Number of organs.	Weight in grammes.	Number of organs.
75	1	140 to 159	9
80 to 99	13	160 to 179	4
100 to 119	11	210	1
120 to 139	11	—	—

The consistency of the spleen may be described as being harder than normal, normal, or softer than normal. The post-mortem records of the same series of spleens showed the following:—

Hard, 33. Normal, 9. Soft, 8.

Thus, as shown by this series, the spleen in general paralysis is usually harder than normal.

Now in 80 autopsies performed upon cases of chronic malaria, Kelsch and Kiener [8] found that the weight of the spleens varied from 400 to 1500 g., averaging 914 g. As these autopsies were on cases of chronic malaria the spleens would be fibrotic and firm. Therefore it is clear that a fibrotic spleen in a subject whose spleen would normally weigh from 140 to 200 g. is exceedingly unlikely to rupture, even although it increased in weight to well over 400 g. As the majority of the spleens in the 50 general paralytics examined were fibrotic and, in addition, weighed under 159 g., the probability of rupture must be even less than in normal individuals whose spleens weigh from 150 to 200 g. It is interesting to note that the large proportion of small fibroid spleens is in agreement with the fact that syphilis causes chronic inflammation of the organ (Bosanquet and Wilson).[9]

Risk of Rupture in the General Paralytic.

From the pathological evidence, therefore, it would appear that the occurrence of spontaneous rupture of the spleen in general paralytics treated with malaria must be even more infrequent than in non-paralytics suffering from malaria, in whom the accident is very rare (Osler).[3]

Although the pathological evidence points very strongly to the occurrence of spontaneous rupture of the spleen as being a very rare phenomenon in general paralytics, it is to the clinical evidence that we must turn for definite information as to whether the risk of rupture is very grave. On reference to the literature, no note as to the occurrence of splenic rupture has been found in the description of 84 cases of malarial treatment dealt with by Yorke and Macfie,[10] of 14 cases described by Worster-Drought and Beccle,[11] or the 12 cases observed by McAlister.[12] In addition, no instance of rupture has occurred in the 39 cases treated with malaria at Claybury Mental Hospital, although many of the patients were old, feeble, and bed-ridden. Although no definite statement can be made as to the frequency with which spontaneous splenic rupture is likely to occur in general paralytics treated with malaria until a far greater number of cases have been watched, it would appear from both the pathological and the clinical evidence that the condition must be exceedingly rare and the risk of rupture in any individual person negligible.

The above observations refer to spontaneous rupture only, not to injury caused by trauma. The frequency of occurrence of the latter would be determined by the restlessness of the patients, the skill of the nursing staff, and similar factors.

In conclusion, I wish to express my thanks to Dr. G. F. Barham, Medical Superintendent of Claybury Mental Hospital, for permission to publish the above facts from the records of the hospital.

Addendum.

Since the above was written the investigations carried out by Bigland, Watson, and Bigland [13] have been published. These observers found an increase of fibrous tissue in the spleens of all but nine of 399 subjects examined, thus giving a higher percentage (97·6 per cent.) than was obtained from the Claybury records (66 per cent.). In both series of figures male and female general paralytics are included.

In three subjects the condition of the spleen following malarial treatment has now been observed. In each instance the cessation of the malarial paroxysms had occurred more than three months before the death of the patient. Two of the organs weighed 200 g. each, the third 100 g. In each organ the splenic pulp was very soft and "mushy" with a purplish tint. In addition, in two of the three spleens a large amount of fibrous tissue was present, causing a very marked grating sensation on cutting into the organ. The structures therefore showed an unusual combination of excess of fibrous tissue with a very soft pulp. A soft "mushy" pulp is very rare in untreated general paralytics.

A CASE OF
CONGENITAL MALARIA OCCURRING IN ENGLAND.

By J. LLEWELYN JONES, M.D., B.Sc. Lond.;
AND
H. C. BROWN, C.I.E., M.B., B.Ch. Camb.,
MAJOR, I.M.S. (RET.),
WELLCOME BUREAU OF SCIENTIFIC RESEARCH.

As some divergence of opinion still exists on the possibility of direct transmission of malaria from the mother to the child, an account of a case which occurred in England may be of interest.

The literature on the subject of congenital malaria contains views and statements which are diametrically opposed. On the one hand we have the opinion of Rosamond[1] (1923) that hereditary transmission of malaria does not take place. Hitte[2] (1909) has described malaria parasites in the blood of the umbilical cord in two cases, but in the article on Malaria in Allbutt and Rolleson's "System of Medicine" Prof. W. S. Thayer pronounces the evidence unconvincing. Grabham[3] (1904) daily submitted to prolonged and repeated search the blood of infants born of malarious mothers, who at the time of birth were heavily infected with both malignant and quartan parasites, but failed to find them or any evidence of malaria, and he concludes that the cases mentioned by Dinstl[*] and others must have been bitten by mosquitoes after birth, although he states that hæmorrhages may possibly take place in the placenta and let loose a number of parasites into the fœtal circulation. Pennato[4] (1921) cites the case of a mother who died at childbirth from malaria whilst the fœtus was apparently free from the slightest indication of it, and concluded that the protecting action of the placenta evidently varies from case to case. This author quotes the observation of Ugo Soli, who reports the protection of the fœtus from acute mercury poisoning which was fatal to the mother. Pennato remarks that our knowledge of the functions of the placenta is not yet sufficient to warrant any dogmatic conclusions as to why malaria sometimes is and at other times is not transmitted to the offspring of infected mothers.

Previous Records.

We now come to a series of cases in which the probability of congenital malaria having occurred seems to have been established.

Forbes[5] (1923), in recording a case in which quartan malaria occurred in an infant in a district in which anopheles had never been found, draws attention to the rarity of intra-uterine infection with the malaria parasite, stating that up to 1910 Beekel found only 12 examples of undoubted placental transmission of malaria on record, and that since then 15 more conclusive cases have been published. He concludes that symptoms appeared at various stages, the longest postnatal interval being seven weeks. A new-born child may, therefore, have a relatively latent type of malaria, and it is probable that some at least of the cases of malaria in infancy, hitherto attributed to postnatal infection, were in reality acquired in utero or at birth. Weston[6] (1922) states that he has seen malaria in an infant five days old, and Cuadra[7] (1920) records a case in which the mother had a malarial history with typical chill and fever two days after the child was born, the child's temperature rose at the same time to 104° F., and *Plasmodium vivax* was cultivated from the blood of both mother and child. Clark[8] (1915), in a study of 400 cases, found that the placental blood showed malarial parasites in 19 cases, whereas the maternal peripheral blood only showed infection in eight cases. Thus the placental blood revealed malaria in 11 cases in which the peripheral blood was negative. Out of these cases the blood from the umbilical cord only showed infection in one case. These observations bear out the view that, under normal conditions, the maternal and fœtal bloods never come in contact.

From the foregoing it would appear that although direct transmission is apparently possible it is a very rare occurrence. The case in which there is little doubt that it was one of direct transmission is as follows:—

Account of a Case.

The mother, who had returned to England from a visit to the continent, and had never been further east than Venice, gave a history of irregular attacks of fever during the last two months of pregnancy. The diagnosis in this case was somewhat obscured by the fact that there was a marked bacilluria with some of the symptoms attending that condition. On the day after a full-term child was born the mother's temperature rose to 104° and splenic enlargement up to three fingers-breadth was present. On examination of the peripheral blood a fairly heavy infection of benign tertian parasites was found. The temperature of the child remained within normal limits until the sixteenth day, when it rose to 104·8°, there was a marked icteric coloration of the skin, and on examination of the finger blood a heavy infection of benign tertian parasites was seen. Numerous gametocytes were present, as many as four being found in one field. Both the patients responded satisfactorily to quinine.

This case occurred in Buckinghamshire, and we are not aware of the presence of any anopheles in this particular locality. Although in the case of trypanosomiasis there is a possibility of infection of the child through the milk, it seems unlikely that infection in this case took place in this way, and judging by the time required for the development of the numerous gametocytes present the most obvious assumption is that this is a case of congenital malaria.

THREE CASES OF
FUNCTIONAL MENTAL DISORDER DUE TO TOXÆMIA FROM THE BOWEL
IN WHICH DECEPTIVE SIGNS OF ORGANIC DISEASE EXISTED.

By JAMES WALKER, M.D., Ch.B. Edin.,
D.P.H. Liverp.,
SENIOR ASSISTANT MEDICAL OFFICER, CARDIFF CITY
MENTAL HOSPITAL.

The subject of intestinal toxæmia has of recent years attracted attention, with the object of confirming or refuting the claim that it is an important factor in the causation of disease. It is hoped that the three cases to be described will confirm the importance of toxæmia in producing symptoms and signs of disease affecting particularly the nervous system. Although the response to treatment in each case shows that the symptoms were due to disordered action of the bowel, it is to be carefully noted that when these cases came under observation the symptoms were more than suggestive of organic disease.

A Case of Hypochondriasis.

Intestinal hypochondriasis is a fairly common complaint, chiefly found in people past middle life. Although, like hysteria, hypochondriasis is only a name applied to a syndrome of subjective symptoms where actual disease cannot be found, it is the duty of everyone to try and find a physical basis for these symptoms. In the following case of hypochondriacal melancholia a definite physical cause was discovered, thus affording striking evidence of the value of the employment of every possible method of examination when dealing with cases whose symptoms appear to be solely subjective.

The case is that of a female, aged 63 years, in whom there s a history of a previous attack of melancholia nine years ago, but no inherited mental instability. On admission to hospital on Dec. 20th, 1923, her mental symptoms consisted more of apathy than of depression. Mentation and conversation were sluggish, but there was no disorientation. Physically she was undernourished, her weight being 6 st. 6 lb. No gross physical disease was discovered except a slight thickening of the radials and a decided distension of the abdomen. The urine was free from albumin and sugar.

The subsequent history of the case is as follows. On account of the abdominal distension, and remembering the requency with which constipation is associated with acute mental disorder as first seen, this patient was given an ordinary enema followed by a saline purge. These measures proved effective, and next day there was marked improvement in the mental state, with almost complete disappearance of abdominal distension. Attention was again drawn to the patient seven days later by the reappearance of mental symptoms in the form of excitement, mild restlessness, and nsomnia. Examination showed that the abdomen was again distended, the patient remarking that she had a "blockage of the back passage." There was tenderness and pain in the region of the middle part of the descending colon. Under the circumstances one was not justified in ignoring the patient's statement about blockage of the back passage. Rectal and abdominal examination gave negative results.

The patient was now placed on a purely milk diet with morning and evening doses of liquid paraffin. There was again decided mental and physical improvement, but a surgeon was consulted as to whether there was any likelihood of a growth in the wall of the descending colon to account or the condition. The surgeon was of this opinion, and a barium meal gave corroborative evidence. There was marked delay in passage through the colon, and it was 54 hours before any of the barium had reached the rectum. In none of the films was any barium seen in the middle part of the descending colon. The patient continued to manifest no mental disturbance while under treatment, and therefore was discharged from hospital one month after admission. She and her relatives were advised to seek surgical treatment in he local general infirmary.

The subsequent history is as follows. She attended the nfirmary for observation and treatment, and in due course the obstruction passed away without the necessity of surgical nterference. On August 18th, 1924, she was visited at her home and was found to be very cheerful and performing her usual domestic work. She informed the visitor that her bowels were acting quite regularly.

The evidence in this case is strongly in favour of a physical basis for the symptoms of hypochondriasis. A toxæmia secondary to the morbid condition of the alimentary tract is the most reasonable explanation of the mental symptoms, especially in a constitution ikely to be more susceptible on account of a former attack of melancholia.

A Case of Toxic Psychosis Simulating Clinically General Paresis.

This case is interesting for two reasons. It shows, first, how important it is to search for every possible source of toxæmia in every patient under treatment for mental symptoms, and second, the value of employing every means of investigation, including that of the laboratory, to enable a satisfactory differential diagnosis to be made.

The patient is a female, aged 52 years, married, and uffering from a first attack of mental disorder, the duration of which is given as six weeks. She was admitted to hospital on Jan. 22nd, 1924. From the medical certificates accompanying her admission we learn little except that her husband states that he has noticed a loss of memory. The family and personal history is interesting. Her parents died in old age, although her father was given to drinking heavily. Patient had one child who died in infancy, and had one miscarriage. She herself is a seven months child, was anæmic at puberty for two years, had suffered on two occasions from rheumatic fever, and had gastric trouble for 20 years, which is reported to have commenced with a hæmatemesis. There is also a history of a definite physical stress. She was on her husband's ship at the time this was torpedoed in 1917. The patient has lived for several years alone during her husband's absence at sea, and during that time has indulged freely in alcohol, consuming at least two bottles of whisky per week. The relatives noticed that for seven months prior to admission she was unsteady on her feet, and suffered from pains in the legs, feet, and fingers, and from vomiting at irregular intervals. This information was not available for over a week, and meanwhile the patient was subjected to a general physical examination, the alimentary tract radiographed, and the usual serological tests performed in the blood and cerebrospinal fluid.

Physical examination revealed the following phenomena. She was extremely emaciated, and her skin so sallow as to resemble some degree of bronzing. Her fingers and toes were cyanosed, with some patches of local anæmia. Nothing abnormal was found in the rsspiratory system. Beyond a decided impairment in the force of the heart's beat nothing of note was found in the circulatory system. The radial arteries were not thickened, and the systolic blood pressure was 122 mm. Hg. The abdomen was retracted, and on pressure definite tenderness was elicited in the epigastrium and along the course of the colon. The knee-jerks were practically absent. The pupils were normally placed and of regular outline, but failed to react to light, direct and consensual. There was a decided tremor of the tongue. Some impairment of articulation and blurring of test-words may partly be accounted for by the absence of teeth. As far as it was possible to test cutaneous sensibility, anæsthesia to pin-pricks was found below the knees. Foot-drop was not present. Patient was ataxic and was unable to walk without falling. During the fortnight after admission it was not possible to get any information or help from the patient on account of the extreme degree of mental confusion present.

Two days after admission the alimentary tract, following a barium meal, was radiographed. This examination showed that the stomach was so proptosed as to be lying deep in the pelvis, was atonic, and showed delay in emptying. There was stasis at the ileo-cæcal junction. Marked stasis was evident in the colon with spasticity of the splenic flexure and descending colon. The Wassermann test was negative in the serum and cerebro-spinal fluid, and in the latter the Ross-Jones test was negative.

Differential Diagnosis.—Excluding the family history and the results of the serological examination, the symptoms made one think of two possible pathological conditions —namely, a toxic psychosis and general paresis. There were several symptoms present which are common to both these conditions—e.g., absence of knee-jerks, tongue tremor, ataxia, as well as the mild degree of mental exaltation that developed during the first week of residence in hospital. In favour of a toxic psychosis, in addition to the symptoms just mentioned as being common to both conditions, there is the peripheral anæsthesia, the emaciation, the sallowness of the skin, the result of the radiological examination, and the negative serological findings. The history of excessive consumption of alcohol and of 20 years gastric trouble strengthens the diagnosis of toxic psychosis. The condition of the pupils is especially interesting. This is one of the few reliable physical signs found in general paresis. Here the loss of the light reflex was clearly due to some cause other than organic disease of the central nervous system. Besides the toxæmia due to the consumption of alcohol, there is no doubt that the alimentary tract has given rise to toxæmia. The progress of the case will bear this out.

Acting on the view taken that this patient's condition was due to toxæmia, not only alcoholic but alimentary, measures were taken to remove the latter by systematic lavage of the colon, which proved to be urgently required. The former source of toxæmia was easily eliminated by her stay in hospital. A fortnight after admission progressive improvement in the gait and locomotion was noted, the knee-jerks returning, and the pupils again reacting to light. Coincident with these changes there was a corresponding improvement in her mental condition. She was discharged recovered on March 18th, 1924.

In July, 1924, when she was seen again, she was quite normal in every respect, spontaneously remarking that she had never felt better for 20 years, a statement immediately corroborated by her husband.

A Case of Functional Mental Disorder Resembling a Case of Organic Nervous Disease, in whom Alimentary Toxæmia is an Important Causal Factor.

The patient is a female, aged 39 years, married, and the duration of the illness is given as nine months prior to admission. This is her first attack of mental disorder. She was admitted to hospital on Oct. 12th, 1922, and discharged recovered on Jan. 23rd, 1923.

The family history reveals a neurotic heredity. A sister has been weak-minded from childhood, another died from tuberculosis, and a maternal uncle was excessively alcoholic. The personal history is uneventful until two years before the onset of the present mental disorder, when she commenced to suffer from what was described as indigestion. The mental disturbance commenced with depression, and she suffered from the morbid fear that she would get beyond her own control. Prior to admission patient developed weakness of the lower extremities and was unable to walk steadily.

On physical examination patient was found to be generally reduced in health and had marked pallor of the skin. After admission she was too confused to give any account of herself or to help in the examination. The respiratory and circulatory systems were normal. There was no enlargement of the thyroid gland. Tremor of the tongue was absent. The deep reflexes were exaggerated and equal on the two sides. The gait was unsteady and patient could only walk with difficulty. Speech was defective with certain test-words. It was impossible to test coördination and muscle sense. The pupils failed to react to light, both direct and consensual. Her teeth appeared to be good. The bowels were constipated. The urine showed no abnormal constituent. The Wassermann reaction was negative in the serum and cerebro-spinal fluid, and the Nonne-Apelt test also negative. A fortnight after admission she was sufficiently recovered to enable a radiological examination to be made. This demonstrated marked atony of the stomach with proptosis, delay at the ileo-cæcal junction, and extreme stasis in the colon, with spasticity.

Differential Diagnosis.—In the first place the symptoms resembled in many respects those found in organic nervous disease, and until the serological findings were known it was impossible to exclude the possibility of general paresis. As in the previously mentioned case, the pupillary light reflex was lost and the gait unsteady. Only one possible focus of toxæmia was discovered—namely, the morbid condition of the alimentary tract. The neurotic inheritance is an additional element in this case, and is probably of primary importance, the toxin inciting mental disorder in a constitution hereditarily weakened. It was agreed that this was a case of toxic psychosis.

Progress of Case.—Treatment consisted in the administration of intestinal antiseptics—kerol in capsules thrice daily, intestinal lavage, a milk dietary, and in the later stages diathermy. Shortly after admission patient very nearly developed acute intestinal obstruction, and for about three weeks the bowels failed to act in response to enemata. When this yielded to treatment there was a coincident improvement in her mental condition. Within a week of this, patient was able to be out of bed, and the power of walking progressively returned to normal. During the following month patient became quite well mentally and was discharged from hospital fully recovered after a residence of two and a half months.

For over a year after her discharge she was kept under observation through the out-patient psychiatric clinic at the Cardiff Infirmary under the direction of Colonel E. Goodall. She maintained excellent health during that time, showing no evidence of mental disorder.

Deductions.

The following deductions can be made from the study of these cases :—

(1) The nervous system is susceptible to the influence of toxæmia either of exogenous or endogenous origin.

(2) Toxæmia of intestinal origin is more frequent than is generally accepted, its deleterious action being more easily produced and more marked when the general health is either reduced by previous illness or the powers of resistance impaired by such agencies as heredity, personal neglect and malnutrition, and unhealthy environment.

(3) Provided the toxæmia has not produced definite organic changes, it is quite safe to give a good prognosis. When recovery is complete an attempt should be made to explain to the patient how the illness was caused, in order to ensure a more satisfactory mode of living and at the same time considerably lessen the chances of recurrence.

In conclusion, I desire to thank Colonel E. Goodall, medical superintendent, for permission to publish these notes, and for valued criticism during their compilation.

IRON DEFICIENCY AND ITS POSSIBLE RELATIONSHIP TO HUMAN DISEASE.

BY J. P. McGOWAN, M.D., B.Sc. EDIN.

(From the Rowett Research Institute, Aberdeen.)

IN previous communications[1] an important and widespread disease in young pigs has been described. This has been shown to be ot the nature of an anæmia of the chlorotic type, induced by a lack of iron in the milk of the sow. The milks of all animals, especially when subjected to artificial selection and rearing, ideal as they are as a food in other respects, have this drawback in common, that they are relatively poor in iron.[3] In young, fast-growing animals, such as the suckling pig, living for a time entirely on milk, the effect of this deficiency can be readily seen. The consequences, however, can be kept in check by causing them, by one means or another, to ingest ferric oxide during the period when they are entirely dependent on their mother's milk—i.e., during the first three weeks of life. Iron deficiency, apart from causing death in an acute form and the production of "wasters," forms the basis for the appearance of cotton-seed meal injury or poisoning, a condition which has greatly hampered the utilisation of cotton seed as a food for pigs in the United States.[2]

In the investigation of iron deficiency in pigs some points have been elicited which may have a bearing on human pathology. It is proposed to indicate these briefly.

The Ætiology of Chlorosis.

It has already been stated that the disease is of a chlorotic nature. While mild cases do occur, the fatality of the condition and the degree of the pathological changes may be much greater than are those usually associated with chlorosis in human beings. The disturbances, however, are of the same nature, and their severity may be somewhat discounted in the comparison if one takes into consideration the difference in age period and growth potential of the suckling pigs and the fact that advanced cases of chlorosis are rare, and those examined post mortem rarer still. Clifford Allbutt,[4] in an exhaustive survey of the literature, subjects the conditions alleged to have a bearing on the ætiology of chlorosis to a minute examination, and, as a result, concludes that chlorosis is part and parcel of the changes that occur in women at puberty. Every girl, he thinks, may be regarded as potentially chlorotic, and perhaps, he suggests, none pass through womanhood without some phase of the disorder showing. Lloyd Jones[5] thinks that chlorosis is the exaggeration of a fertile blood—of blood, that is, which has for its end the storage of nutritive material for the fœtus during pregnancy. The changes in the blood in chlorosis he thinks, are an extreme fluctuation of a physiological quality of the child-bearing period of life He suggests that the immediate cause may be a profusion—a toxic excess—of an internal secretion from the sexual glands. Campbell,[6] as the result of an elaborate study of cases at Guy's and other hospitals in Britain, comes to much the same conclusions as the authors just mentioned. These views, while indicating the important part that sex and puberty play in the origin of the disease, would appear to be somewhat fatalistic, regarding chlorosis at any rate in its mild form, as necessary, and not an evil, in the sense that it forms part of the essence of fertility. These opinions, however, seem to be discounted by the great decrease of chlorosis within recent years,[6] without there being anything to indicate that fertility has been reduced at the same time.

The disease may be regarded from another angle and another theory of its nature suggested Stockman[7] has shown that the habitual diet of certain chlorotics, which he examined, was very poo in iron. Baillet[8] has shown that in women a puberty, as compared with men of the same age, there is a critical fall of the amount of iron in the liver. Having regard to the known facts, this cannot mean that less iron is required, but either that iron is being used up at a greater rate or that less iron is being absorbed. In the iron deficiency in pigs it was very noticeable that the more rapidly growing pigs, in which metabolism would be proceeding at greater rate, were most severely affected with the disease. It is usually assumed that increased metabolic activity, associated with the development of various organs, characterises puberty.[9] Various explanations have been given for the great decrease in the occurrence of the disease within recent years, noted by all recent writers (Price,[10] Campbell (loc. cit.)). Having regard to the points just enumerated and in consideration of the dual function of iron in the body referred to later, chlorosis might be regarded as the expression of a real lack of iron in the tissues of the body. It could be supposed that the changes at puberty might produce an increased demand for iron in the tissues to cope with the increased metabolic activity at this time. This might not be forthcoming in the habitual diet, in which it may be assumed no change has been made to meet the onset of puberty. This could initiate a condition of ill-health, characterised possibly by indefinite symptoms, among which almost certainly would be a diminished or depraved appetite, which would lead, on its part, to a further diminished intake of iron. There would thus be initiated an ever-widening vicious circle by means of which the disease condition would become more and more stabilised or fixed owing to organic changes, due to the lack of iron, taking place in tissues such as the liver, more fixed in type and less labile than the blood.

In this connexion attention may be drawn to the tendency for remissions to occur in chlorosis and to a possible explanation in terms of what has just been said. The hæmoglobin of the blood can easily be restored to normal by the administration of iron. The patient, however, is not necessarily cured when this has been accomplished, and a prolonged course of iron administration is usually found to be necessary. The reason of this may be that the more or less fixed, or more differentiated tissues of the body, having been disorganised by the lack of iron, require a prolonged treatment with it before they can be brought back to a normal condition. Hence the liability for the disease to recur. It will be seen that, in the view expressed here regarding the disease, emphasis is laid not on the lack of iron in the blood, but on the lack of iron in the tissues. With regard to the decrease of the disease in recent years, it could be argued that the changed outlook on life in women, approximating more and more to that of men, has much to do with it. Athletics, outdoor life, &c., by their effect on appetite, together with an improved public opinion as to what constitutes suitable food, might render it less likely that the onset of puberty would be caught, so to speak, unawares in the vicious circle referred to above.

Iron Deficiency and Rickets.

It is possible that iron deficiency may play a part in the production of the *symptôme complexe* of rickets. In this condition there are, in many cases, enlargement and fatty change in the liver, secondary anæmia—in some cases so profound as to resemble that present in chlorosis, and the subjects of the disease are often abnormally fat (Hutchison[10])—all occurrences which are found to a marked degree in iron deficiency in pigs. Milk is very poor as regards its iron content, and the various artificial foods so prone to cause rickets are poorer still.[11] It is not, however, suggested that the lack of iron, of itself, causes rickets, but the view is put forward that it may, by simple addition, modify considerably the picture of the disease as it is seen clinically. If regard, however, is had to the importance of iron in ultimate tissue metabolism, it may quite well be that the picture is not one of the simple algebraic sum of rickets and chlorosis. They may interact, and mutually aggravate one another. In this connexion, and as an instance of how the two conditions may clash locally, may be mentioned the changes occurring in relation to bone in these two diseases.

Pathological Changes in Iron Deficiency in Pigs.

The pathological changes, present in iron deficiency of pigs, include in varying degrees of intensity and in varying combinations the following: anæmia, enlargement of the heart, effusion of fluid into the various serous cavities, and fatty change and necrosis of the lobules of the liver. In the earlier stages of the disease, which may, however, be severe enough to cause death of the animal, there may be present nothing more than anæmia, enlargement of the heart, and effusions into the various cavities. Such cases have a considerable resemblance to those of wet beri-beri in human beings, and it is a suggestive fact in this connexion that whereas rice bran contains 0·232 per cent. of iron, polished rice contains only 0·003 per cent.[11] Beri-beri is usually attributed to a lack of vitamin B, but it may quite well be that the ætiology of wet and dry beri-beri are different, and up to the present there is no proof that they are the same.

On the other hand, in the advanced cases of the disease, the changes occur principally in the blood and blood-forming organs, and in the liver. Advanced anæmia of the chlorotic type is present, while the liver is greatly enlarged and altered. The individual lobules are either in a state of advanced fatty change or have been destroyed for the most part and their place taken by blood. On regeneration the liver shows cirrhotic changes.[12] Such cases resemble those of toxic jaundice due to poisoning with such substances as tri-nitro-toluene, &c. (Panton,[13] Stewart[14]), where the brunt of the action also falls on the liver and the blood (Wyon[15]). From such considerations as these the suggestion might be made that such poisons produce their effect by putting the iron in the tissues out of action.

Roger [16] has emphasised the dual action of iron in the body—as a constituent of hæmoglobin, and also as taking a part in the life functions of every cell in the body and especially of the liver cell. The conditions found here would appear to support and emphasise this view, which again, vouched for by an authority like Roger, has been used in the explanation of some of the phenomena dealt with above.

VOCAL THERAPY SOCIETY.—An address will be given at the Royal Hospital, Chelsea (Governor's House, East Gate), on Wednesday, Nov. 26th, at 5 P.M., by Sir Henry Hadow, Mus.D., Principal of Sheffield University, on the Healing Influence of Music exemplified in medical treatment combined with the Vocal Therapy Society's training in concerted singing. Lord Blanesburgh will take the chair. Members of the King's Services Choirs from Ewell Ministry of Pensions Hospital will sing. Free tickets for admission may be had on application to the Secretary, V.T.S., 27, Grosvenor-place, S.W. 1.

ON THE INFLATION TEST FOR TUBAL PATENCY

AND A SIMPLE INSTRUMENT FOR CARRYING IT OUT.

BY VICTOR BONNEY, M.S., M.D., B.SC. LOND., F.R.C.S. ENG.,

SURGEON, CHELSEA HOSPITAL FOR WOMEN; ASSISTANT GYNÆCOLOGICAL SURGEON, MIDDLESEX HOSPITAL, ETC.

THE test for tubal patency by inflation from below in cases of sterility is now commonly employed in the United States, and is gradually being taken up in this country. The apparatus favoured in America, an example of which was demonstrated at the annual meeting of the British Medical Association last year,[1] consists of an arrangement whereby carbon-dioxide gas can be passed into the uterus through a tube to which is affixed a cone-shaped indiarubber obturator. This obturator is kept firmly pressed into the external os, whilst the gas is being injected so as to prevent its backward escape. A manometer is attached to the apparatus, and the pressure shown indicates whether the gas is freely passing into the peritoneal cavity or not. If the tubes are patent a pressure not much over 100 mm. of mercury should be registered. Confirmation of the passage of the gas can be obtained: (1) by hearing through a stethoscope the gas escaping from the abdominal ostia; (2) if the patient is not anæsthetised and sufficient gas be introduced, by her complaining of pain in her right shoulder due to vagus disturbance, a proceeding which does not commend itself to me; and (3) by examining the abdomen with the fluoroscope after injecting a considerable quantity of gas into the peritoneal cavity.

My colleague, Arthur Gray, pointed out to me that such an elaborate apparatus was not necessary, and that equally reliable results could be obtained by injecting air by means of a simple rubber bulb, attached to which was a metal tube furnished with a rubber obturator. The tube, having been inserted into the uterus and the obturator pressed into the external os, the degree of resistance experienced by the hand compressing the bulb indicated quite clearly, not only whether the air was passing into the abdominal cavity or not, but whether, if passing, it passed with normal ease.

As a result of trying Gray's apparatus I bethought me of a device whereby the obturator could be dispensed with, for it was difficult entirely to prevent the injected air leaking past the obturator when the cervix was deformed, and it was impracticable to keep the obturator pressed against it with the abdomen opened in the Trendelenburg position, though, as I shall presently show, it is most desirable to be able to inject air under these conditions.

The instrument I had made consists of one-half of a Fenton's dilator, size 7, with a channel running through it from end to end, closed during the introduction by a stylet. Attached to the dilator by means of an air-tight push-joint is a rubber tube and bulb, which by a T-piece connects with a manometer, like that used with a sphygmograph. (See Fig. 1.)

Method of Use.

The method of using it is as follows: Under anæsthesia the cervix is dilated in the usual way, but instead of the ordinary No. 7 Fenton being used, the perforated dilator is introduced instead. The stylet is then withdrawn, and the rubber tube, bulb, and manometer is attached to the proximal end of the dilator. The bulb is then steadily compressed with the hand, and the resistance encountered is noted on the manometer. Such is the pressure of the cervical wall against the dilator that no air escapes backwards between them, even under strong pressure. The point to be ascertained is whether the bulb can be emptied without undue exercise of force for, if it can be, then the air must have passed into the peritoneal cavity. It is quite unnecessary, and in fact undesirable, to empty the bulb more than once.

In practice one of four things happens:—

1. *The bulb is emptied without any difficulty, the pressure not rising much above 100 mm. at any time and falling to zero by the time the bulb is empty.*—This indicates that one or both tubes are freely patent; a finding which in a case of sterility at once contra-indicates any abdominal operation having for its object the opening up of the tubes.

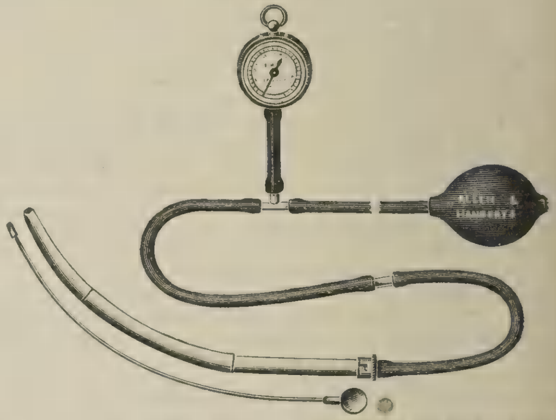
2. *The bulb cannot be emptied, although the pressure is raised to 200 mm.*—Above this it is not safe to go, for fear of rupturing the tubes or uterine cornua. Such a finding shows that both tubes are blocked, and in a case of sterility indicates that an attempt should be made to reopen them through the abdomen. A small amount of air can be forced into the uterus by distending its cavity, but not enough nearly to empty the bulb. I have been able to observe what happens when the uterus is inflated under these circumstances and find it is the cornua which distend, the uterine wall in these regions being relatively thin and stretchable.

3. *The bulb empties but with difficulty, the pressure required being well above 100 mm., but when emptied the pressure falls to zero.*—This shows that there is a partial block, the air escaping into the peritoneal cavity very slowly. In a case of sterility here, as in the preceding, an abdominal operation is indicated.

4. *The bulb empties with difficulty, the pressure required being well above 100 mm., and when empty the manometer continues to register a definite pressure.*—This shows that the air has distended a tube closed at its abdominal end only, the pneumo-salpinx thus formed acting like the compressed bulb and continuing to maintain the pressure. An abdominal operation is indicated.

The dilator, the bulb, and the tubes are sterilised by boiling, the manometer being subsequently attached by means of a separate unboiled section of tube. It might be suggested that the injection of air carries with it the risk of infecting the tube with air organisms. A moment's consideration will show that if there was such a thing as air-borne septic infection no surgical operation would be safe. As a matter of fact, the experiments carried out by Andrews some years ago showed that air, when collected from such a crowded thoroughfare as Oxford-street, does not contain the organisms of common sepsis. It is probable that every time uterine dilators are used a certain amount of air is forced into the tubes if their inner ostia be patent. A more cogent objection is the possibility of blowing into the tubes septic organisms derived from the vagina or cervix, and where definite infection of these is present inflation should certainly not be carried out, nor for that matter dilatation of the

FIG. 1.



The apparatus designed for carrying out the inflation test for tubal patency.

---

[1] Gilman Currier: Jour. Obst. and Gyn. of British Empire, vol. xxx., No. 4.

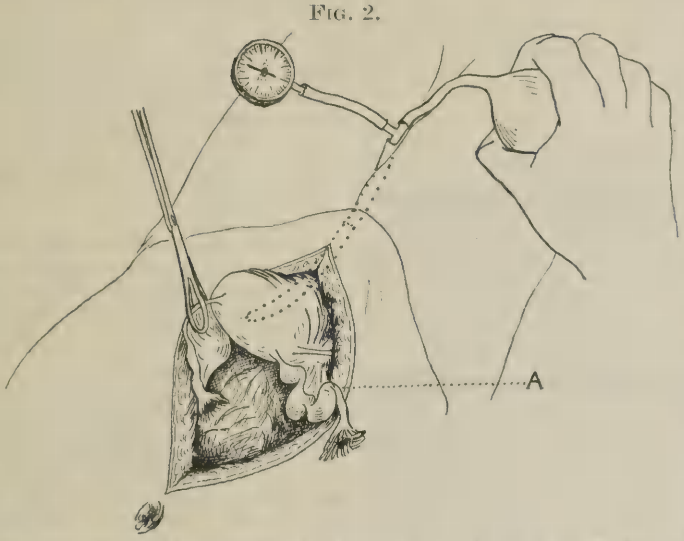
cervix either. For the rest it would appear from the now large experience of American surgeons that infection of the tubes does not occur, and this is what I and my colleagues have also found.

Inflation with the Abdomen Opened.

Suppose, then, that the operator finds either a deficient passage of the air or no passage at all. The dilator with the bulb attached is left in the uterus and secured there by packing gauze into the vagina round it. The abdomen is then opened and the condition of the tubes inspected. A ring forceps is now placed on one of them so as to close it securely, and an assistant then compresses the bulb so that the surgeon can see what happens to the other tube. (Fig. 2.) If the block is at the inner ostium no air at all enters the tube, but if it be further along, the tube will be seen to dilate as far as the block. The ring forceps is now taken off and applied on the other side and the condition of the second tube is investigated in the same way.

The surgeon has now to decide whether he should open up the tubes or one tube only, or neither according to the condition found. I do not propose to discuss the various methods of making a new outer ostium, or of establishing patency when a long length of the inner end of the tube is occluded. Different conditions require different measures, and the surgeon must adapt himself. Suffice it to say, that for some time past I have in most cases simply slit the tube along its free border and continued the slitting until air driven in from below escapes freely into the abdominal cavity. I do not suture the edges of the slit, but simply compress them with a swab and let them lie until all oozing has stopped. In most cases this can be done, and it has the advantage of leaving no foreign-body sutures to cause subsequent adhesion.

Fig. 2.



Testing the right tube with the abdomen opened and the patient in the Trendelenburg position. The tube is obstructed at A.

What Inflation Teaches.

The most important thing that inflation teaches is that in an unexpected proportion of cases of sterility the tubes are not freely patent, although tactile examination reveals nothing apparently abnormal about them. When one comes to examine such tubes through an abdominal incision, the blockage is found to be due either to closure of the abdominal ostia by adhesions, or to stricture, usually multiple, along the course of the tube, or to kinks in the tube. All these conditions are probably, in most cases, the after-results of inflammation, but of inflammation so slight that the patient's past history can be searched without finding any clue pointing to the date of its occurrence. That the original trouble is sometimes tuberculous is proved by the not infrequent finding of tiny nodules on the peritoneal surface of the tube or mesosalpinx, but of so mild and transient a nature must the infection have been that no symptoms were at any time produced. In other instances slight salpingitis, producing no more than a transient stomach-ache, may have followed an infected miscarriage, or have been a sequence to non-venereal streptococcic or staphylococcic cervicitis or even to gonorrhœa. As a rule, however, this is mere supposition, for the history is silent.

It is noteworthy that many of these closed tubes present an appearance so like the normal that close inspection is needed to see the deformity. This particularly applies to kinks. A kinked tube presents a series of slight moniliform dilatations, the sections intervening between which mark the points where the mesosalpinx is shortened. On inflating the tube from below these appearances become very much more marked. The mesosalpinx at the points of shortening often resembles on a minute scale the mesentery of kinked intestine in that it exhibits fine tethering bands.

The mechanism of the production of tubal kinks probably varies. In some cases multiple strictures due to salpingitis lead to dilatation of the tube between the strictures, with elongation of the mesosalpinx at the seat of dilatation and relative shortening at the points of stricture. In other cases local shrinkage of the mesosalpinx is probably the first happening, and this, by kinking the tube, obstructs it and leads to dilatation of those sections not kinked. Finally, both processes may go on together. Whichever way it happens the kinks play a large part in the obstruction, for it often happens that on straightening the tube by pulling and stretching the mesosalpinx, while inflation is being carried out, the obstruction disappears and the air passes through the abdominal ostium.

This leads me to an effect of retroflexion. I am of opinion that this displacement is responsible in some cases for kinkage of the tubes, at first merely by causing them to assume abnormal curves and angles, which later on become permanent owing to organic alterations in the mesosalpinx, a parallel, in fact, to what happens with displaced intestine. It is certain that I have now had several cases in which air refused to pass with the uterus in retroflexion, but passed readily enough directly the displacement was rectified through the abdominal wound. If my observations prove to be of general application, they afford one explanation of the sterility so often associated with retroflexion.

Finally, inflation of the tubes in some cases aids the surgeon in diagnosing the nature of a pelvic mass. As an example, if a swelling is found on either side of the uterus and on inflation the bulb can be emptied, showing that one at least of the tubes is patent, then the mass on one of the sides is not tubal. I had such a case lately which on opening the abdomen exhibited bilateral ovarian blood cysts, the tubes being strongly adherent to the cysts, but in themselves both quite normal and patent.

Fellowship of Medicine and Post-Graduate Medical Association.—A special course in infants' diseases (for medical officers of welfare centres and others) will be given at the Infants Hospital, Vincent-square, Westminster, from Dec. 1st to 13th. The names of qualified practitioners wishing to attend the course (the number will be limited to 15) should be sent to the secretary of the Fellowship at 1, Wimpole-street, W. 1.

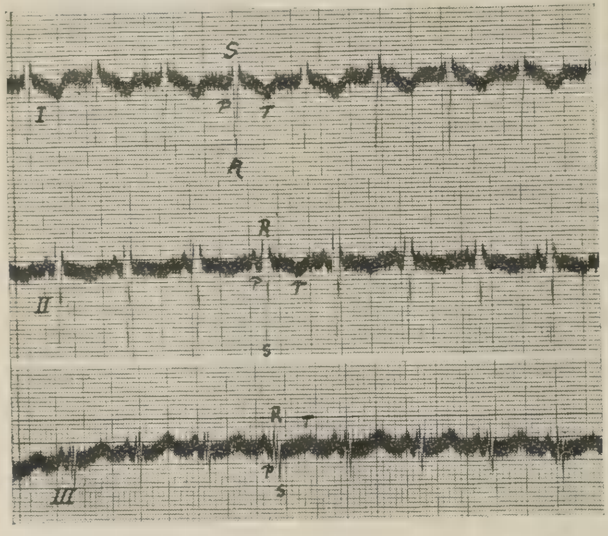
Clinical and Laboratory Notes.

CONGENITAL AND ACQUIRED DEXTROCARDIA.

A CASE COMBINING BOTH TYPES.

BY A. I. G. McLAUGHLIN, M.B., CH.M. SYD.,
FORMERLY RESIDENT MEDICAL OFFICER, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK.

Wallace Jones [1] defines dextrocardia as a "condition in which the heart beats in a more or less permanent manner in the right half of the thorax." Cases of dextrocardia are usually subdivided into (1) inversions, or "mirror image" of the heart; and (2) dextroversions, where the heart is displaced to the right without inversion of the cavities. Inversion of the heart is invariably congenital in origin. Dextroversion may be congenital, but is more frequently acquired.



Electrocardiogram of a case of dextrocardia. Inversion of lead I. and transposition of leads II. and III.

The following case is unusual in that it combines the features of both congenital and acquired types.

The patient, a male, aged 22, was admitted to hospital on August 13th, 1923. His symptoms were cough, sputum at times slightly blood-stained, shortness of breath, night sweats, and slight loss of weight. His previous illnesses were measles and whooping-cough at 6 years of age, and an attack of right-sided pleurisy in January, 1923, since when he had suffered from a persistent cough.

Examination of the chest revealed the presence of dextrocardia, the apex beat being 4½ inches to the right of the midsternal line in the fifth intercostal space. Marked impairment of the percussion note was elicited at the base of the right lung, together with amphoric breath sounds, whispering pectoriloquy, sharp consonating crepitations, and the peculiar squeaking sucking sounds, described as being characteristic of fibrosis of the lung by Clark, Hadley, and Chaplin.[2] An interesting feature was that consonating crepitations could also be heard in exactly corresponding situations on the left side of the chest, without any accompanying impairment of the percussion note. This would suggest that the sounds were conducted from the right side. At the right apex the percussion note was somewhat hyper-resonant and the breath sounds were tinkling in character, suggesting the presence of a localised pneumothorax, or possibly a very large cavity in the upper lobe of the lung. Tubercle bacilli were found in the sputum. On examination of the abdomen, the stomach was found to be on the right and the liver on the left side.

The electrocardiogram (see figure) presented the typical appearance of a true dextrocardia—i.e., inversion of lead I., with transposition of leads II. and III. A radiogram showed the displacement of the heart to the right, a dense opacity at the right base, and at the apex a large cavity, traversed by several strands, presumably blood-vessels.

Points in Diagnosis.

Briefly, the patient had complete transposition of the viscera, basal fibrosis, and apical cavitation of the right lung, with either primary or superadded tuberculous infection. The interesting points in the diagnosis were :—

1. The dextrocardia could be explained either by complete transposition of the viscera or by the basal fibrosis. The amount of cardiac displacement was more than is usually found in uncomplicated inversion of the heart. It was increased by the dextroversion due to the fibroid changes in the lung. The combination in one case of two causes of dextrocardia is probably very rare.
2. The fibrosis of the lung may possibly have commenced after measles and whooping-cough in childhood, or after the right-sided pleurisy in January, 1923. There was, however, no definite history of broncho-pneumonia following the measles and whooping-cough, and the usual signs of long-standing fibrosis of the lung were not present. The bulk of the evidence is in favour of the fibrosis being of pleurogenetic origin, dating from the pleurisy of January, 1923.
3. The condition present at the right apex might have been a localised pneumothorax, or a very large lung cavity. The physical signs suggested a localised pneumothorax, but the radiogram favoured cavitation. The subsequent onset of copious hæmoptysis also indicated that a cavity and not a localised pneumothorax was present.

A further possibility was that the illness of January, 1923, was a tuberculous consolidation of the right lung with subsequent cavitation of the upper lobe and fibroid changes at the base.

I am indebted to Dr. Clive Riviere for permission to publish these notes, to Dr. A. J. Scott Pinchin for the electrocardiogram, and to Dr. F. W. Hamilton, who referred the case to me from the tuberculosis dispensary.

OPTIC ATROPHY DUE TO LATE SYPHILIS.

A NOTE ON THE INTRACISTERNAL INJECTION OF MERCURIC CHLORIDE FOR THE ARREST OF THE CONDITION.

BY GRAYDON O. HUME, M.B., B.S. LOND., D.O. OXF.,
LATE CHIEF CLINICAL ASSISTANT, OPHTHALMIC DEPARTMENT, GUY'S HOSPITAL.

ACCORDING to Fuchs, optic atrophy occurs in 10–15 per cent. of tabetics, the first indication being a gradual deterioration of vision. By perimetric tests contraction of the field of colour vision is found, the limits for green in particular being restricted. Later the field for white becomes smaller, central vision fails, and amaurosis supervenes. The extensive work of Uhthoff and Stargardt emphasises the inconstancy and variability of the deterioration of vision in each individual affected. One fact remains, failure of vision is progressive and remissions never occur.

Affections of the nervous system due to late syphilis respond feebly to intraspinal treatment. There being no circulation in the ordinary sense in the cerebro-spinal fluid, in order to reach the region of the optic chiasma and optic nerves the drug in solution must be injected towards the base of the brain.

Following the suggestion of Dr. S. R. Gifford, of Omaha, U.S.A., I decided to adopt his technique for the injection of mercuric bichloride into the cisterna cerebellaris.

Practice with the lumbar puncture needle on the cadaver in the post-mortem room gives precision in the technique of cisternal puncture. With the patient lying absolutely prone and with the forehead supported either on a brow rest or suspended in a sling, the lumbar puncture needle is inserted in the neck directly over the spine of the second cervical vertebra. The point is directed upwards in the middle line at an angle of about 45°—i.e., towards the mid-point of an imaginary line joining the two external auditory meati. Between the occipital bone and the atlas it pierces the dense occipito-atlantal membrane. When the graduated needle has entered to a depth of 4 to 6 cm., its point is in the angle between the medulla and the vermis. In order to avoid the danger of "plunging," a guard is placed towards the shoulder of the needle. Ten c.cm. of cerebro-spinal fluid are withdrawn, and to half this amount are added from two to five drops of the 0·5 per cent. solution of mercuric bichloride—each drop being calculated as equivalent to 0·25 mg. of the drug. An injection of four drops diluted would thus contain 1 mg. of mercuric chloride. (It is easy to determine the size of the drops by varying the rate of flow from a burette containing the solution.) The mercuric chloride solution further diluted in the 5 c.cm. of cerebro-spinal fluid is allowed to flow into the cisterna magna by gravity. Severe frontal and occipital headache with pallor, sweating, and a fall in blood pressure are the usual sequelæ. It is very desirable to precede or follow up this form of treatment by siphonage of never more than 6 c.cm. of fluid from the lumbar region of the canal; at the same time, an injection of novarsenobillon is made into a vein in the antecubital fossa.

---

[1] Jones, Wallace: Brit. Med. Jour., Jan. 26th, 1924, p. 147.

[2] Clark, Sir A., Hadley, W. J., and Chaplin, A.: Fibroid Diseases of the Lung, p. 102.

Two of my three cases responded somewhat to treatment; in one the course of the atrophy was arrested for some time; in the other its rate was slowed down. Dr. Gifford informs me that he has had a series of cases in which the atrophic process came to a stop following *several* injections, and that some cases had actually improved.

Undoubtedly certain cases of optic atrophy due to late syphilis respond to this form of treatment and the progress of the atrophy is arrested at least for a time. Treatment by cisternal injections is most hopeful when commenced in the incipient stage of the atrophic process. The serious and relentless nature of optic atrophy associated with the late stages of syphilitic infection justifies our attacking the disease by a route which has added risks.

Medical Societies.

HUNTERIAN SOCIETY.

THE MEDICAL WITNESS.

THE Hunterian Society held a discussion at the Cutlers' Hall on Nov. 17th on the subject of The Medical Witness. Mr. H. W. CARSON (President of the Society) occupied the chair.

Mr. Justice HORRIDGE, who opened, said that no one who took part in any way in the administration of justice could exaggerate the importance of the medical witness in courts of law. The medical witness helped the court in every possible way, and his evidence was the handmaiden of justice. In criminal trials, from the simplest assault up to the most serious of crimes, that of murder, the medical witness was frequently called on, and often it was for such a witness not only to consider the facts of the case, but also to judge the criminal's responsibility for his actions. The result in cases concerning wills also often depended more upon the evidence of the doctor than upon anything else, and if a testator was fortunate enough to get his doctor to witness his will the circumstance went a long way to establish that will in the event of dispute. In the Divorce Court and in nullity suits the evidence of the doctor was of first importance. In workmen's compensation cases the doctor as medical referee of the court might be said himself to take part in adjudication. In a vast number of civil cases the evidence of medical witnesses was called on one side or the other. He desired, therefore, to give a few hints to doctors as to the way in which their evidence should be prepared and given. In preparation the medical witness could not be too careful to notice every minute fact even if at the time it did not seem to him to have any importance. Having ascertained the facts he should endeavour to form an opinion from his own scientific knowledge, but there was here a lively danger with regard to which it was necessary to utter a note of warning—the danger, namely, of approaching a case in the first instance with a preconceived idea. Some medical witnesses approached a case with the idea that, for instance, it was a poisoning case, and instead of setting to work to find out all the facts, great or small, and then forming their opinion on the post mortem or other evidence, they started out to see whether the facts of the case fitted in with their preconceived theory. There was nothing so dangerous as that. Their duty was to collect the facts and then to bring their own knowledge to bear. Even after they had formed a definite opinion they should keep their minds open so that should other facts be disclosed in the course of the trial they should be able to mould their opinions even up to their last moment in the witness-box.

Hints to Medical Witnesses.

The learned judge went on to say that in his experience, speaking generally, the fairness with which doctors gave their evidence was quite extraordinary. Often it had happened that when doctors had been standing below under the prisoner's counsel, and had heard the medical witnesses for the prosecution (or for the plaintiff, as the case might be) give their evidence, they had gone out of court because they were not able to contradict a single thing the doctors on the other side had said. The doctor in the witness-box should be on the look-out for the double question. Counsel very often put to witnesses a double question, and if the witness was not careful and gave a simple affirmative or negative the counsel would afterwards use that answer to the half of the question which suited him best. If the witness could give a direct answer, yes or no, he should do so; he was always entitled to qualify it afterwards and to add anything he wished to explain. He would also warn the medical witness against being lured into answering a question on a subject he knew nothing about. He should say that he had not considered the question, and was not in a position to answer it. The medical witness also should endeavour as far as possible to speak in ordinary language. In nine cases out of ten it was sufficient to say that a man was badly bruised; it was not necessary to say that he was suffering from ecchymosis. The use of technical terms often led to the judge or counsel having to explain their meaning to the jury.

Professional Privilege.

In conclusion, he proposed to say a few words about professional privilege. So far as he was aware there were only two classes of persons to whom privilege had ever been granted. It had been granted to solicitors, not on account of any professional status, but because it seemed to be necessary for the administration of justice and the elucidation of truth. Unless people were allowed to have their legal advisers in absolute confidence the machinery of the courts could not go on. The object of that privilege was to facilitate the work of the courts. But even this had its limitations; professional communications in a case of criminal conspiracy were not privileged and had to be disclosed. The second case in which privilege had been allowed was as between husbands and wives. That originally arose from the fact that in former days the wife had no existence apart from her husband, but it arose also from the fact that it would be impossible for society to continue if the relations between husbands and wives could be inquired into. But in recent years Act after Act had made husband and wife eligible witnesses against each other in criminal trials. On what ground should privilege be allowed to the medical profession? In his view there was no ground. The evidence of doctors was required in order to aid the administration of justice. The claim could only be put forward on the ground of confidential relationship, but where was the line to be drawn? Was the nurse who attended the case also to be privileged? Was the chemist who made up the prescription to be privileged? Was privilege to be extended to faith-healers and bone-setters in their relations with their patients? The legislature in two Acts—the Notification of Diseases Act and the Notification of Births Act—both of which, he thought, were passed with the support of the medical profession, required the doctor to reveal, in public, matters which had come to him in his professional capacity. The law was clearly stated by Lord Mansfield, but the speaker would not put it only on the ground of law; in their innermost conscience the doctors must know that they were there to assist in the administration of justice, and it was for that reason that they were protected.

The Need for Impartiality.

Sir William Willcox said that the giving of evidence was one of the greatest privileges of a medical man. The way in which he gave it might affect not only the result of the inquiry, but also his own reputation. In preparation for his evidence he should be careful to notice everything that might have a medico-legal bearing and record it, for memory was fallacious and untrustworthy, particularly as regards exact details. Even a trifling detail might turn out to be one of the most important points in a subsequent trial. His evidence should be given in clear and concise language, suited to persons of average intelligence possessing no special medical knowledge. In the case of expert evidence the doctor should realise that his function was to assist the court of inquiry by his special knowledge and experience. He should not be an *ex parte* witness, and should be absolutely free from bias. This was of supreme importance in criminal cases, but impartiality should be no less important in civil cases. The witness should refresh his memory by the most careful study of scientific literature; if necessary, he should conduct scientific experiments and investigations to elucidate any difficulties which might arise. He should cross-examine himself on every aspect of the question. Here the speaker wished to say what a great advantage it had been to him to have had consultations with counsel before a trial came on; the cross-examinations at these consultations were usually much more searching than those in the actual witness-box. It was an advantage to the expert medical witness to imagine himself in the position of the judge or of the cross-examining counsel and try and regard the subject of inquiry from their point of view as well as from that of counsel on the other side. With regard to medical reports, before being called on to give evidence the expert medical witness should express his opinion on the facts before him in a written report, and the reasons for his opinion should be concisely stated. The opinions expressed in that report should be his inalterable views upon which he had no doubt whatever. Any expressions of opinion on which there was any possibility of doubt should be omitted from such a document. In the witness-box evasions of a direct answer were apt to create a bad impression. A direct negative or affirmative should be given where possible, and if this was not possible the reasons for inability to give a direct answer should be clearly and courteously stated. Lengthy explanations and attempts to give lectures in the witness-box were apt to weaken the evidence. If a double or a triple question was put to him, the witness should ask for it to be suitably divided and make his reply on each section. If statements from books or reports were put to him, the expert witness would be wise to ask to see the work in question. Generally if books were quoted to controvert one's evidence it was possible, with the book in one's hand, to turn the tables. It would often be found that counsel had taken a chance passage out of the book, but that the context or the main argument supported the contention of the witness. Another point was that the expert witness should be in court during the whole of the proceedings. Indeed, it had been ruled that it was necessary for such a witness to hear the evidence. He concluded by expressing, out of his very lengthy experience as a medical witness, his sincere appreciation of the courtesy and consideration invariably extended to medical witnesses by members of the legal profession.

Sir Francis Newbolt, K.C., said that he had found the medical experts almost the only experts who were fundamentally honest, and this he illustrated by cases in which experts on other lines had differed to an extent which he could not regard as an honest divergence. The bias in human nature produced by fighting on one side could not easily be overcome, but he liked to treat such cases rather as inquiries than as dog-fights. In his court it was not possible to bully a witness. This came about largely because there was no jury. No one who had ever sat on the bench could fail to distinguish between the two types of trial. When a judge was trying a case with a jury he had to consider all the time what was likely to be going on in the minds of the jury. If a judge sat alone he made his notes in the most convenient and also most true form by paraphrasing the witnesses, but if he had to sum up to a jury he had to put on his note the exact words used by the witnesses, otherwise he might be accused of garbling the evidence. The speaker added that even the honest experts of the medical profession were not impeccable. He recalled a case when he was at the Bar. In a workmen's compensation case at the county court, when the question was whether a much injured workman had recovered, a doctor called as an expert witness gave his evidence quite decidedly. Some time later the speaker was leading in a case at the assizes when the same doctor appeared on the other side, and in exactly the same circumstances gave evidence contrary to what he had given before. The speaker would not easily forget the disturbed look which came into the witness's face when he reminded him on the second occasion of that earlier encounter. His advice to medical witnesses would be that if they knew their book and were not afraid of anybody they could not be put down nor effectively cross-examined. The great thing to remember was common-sense, and if they could at the same time imagine that they were really appearing for both sides in a case they would make ideal witnesses.

The Dangers of Relying on Precedent.

Sir Bernard Spilsbury thought it might be claimed that the medical profession invariably gave evidence fairly and honestly, and that wilfully misleading or lying evidence was rarely heard from a medical witness. The responsibility of a medical witness in a serious criminal case might not seem so great to the witness himself as to those in court, for in all these cases the evidence was always given impersonally. Doctors were not giving evidence necessarily against the prisoner in the dock, but against the person, whoever he was, who committed the crime. In post-mortem examinations in criminal cases it went without saying that very careful and thorough investigation was required. The expert had not merely to ascertain the facts, he had correctly to interpret them, and it was in this respect that his evidence was of most importance. Members of the legal profession were too apt to think that a doctor had only to observe his facts, but medical men knew that those facts required careful analysis and interpretation before they became the true facts in the case. It was essential in many cases—in almost all criminal cases—that the naked-eye observation of the dead body should be supplemented by microscopical and in a certain proportion of cases by bacteriological examination also. There were a few cases in which the facts were so evident and undisputed that the medical evidence need be little more than formal, but apart from such cases he felt very strongly that skilled expert assistance should be available to the general practitioner. A pathologist should be employed almost invariably. In addition to making a careful examination of the dead body and supplementing that examination by microscopical or bacteriological work, the examiner should always have time and opportunity very carefully to consider the facts he had elicited, and to weigh and compare them with similar facts in other cases, consulting authorities and text-books as required. Only after he had done all this should a medical witness give his evidence in the first—that is, the coroner's—court. With regard to the consulting of authorities, however, the speaker could not help feeling that personal experience based on accurate observation was far more valuable than any text-book. The authority of the text-book should only be supplementary. Text-books themselves were far from infallible, partly because the body of knowledge acquired had been taken from past cases in which the evidence was of very variable value. Moreover, many of these past cases were decided at a time when the knowledge of medicine was far less than to-day. The speaker referred in detail to the famous Palmer poisoning case and the Penge murder case to illustrate how different might be the deductions and conclusions should these cases have been tried to-day, and the danger of relying on older authority for guidance in connexion with recent investigations.

Dr. **EDWIN SMITH** (coroner for N.E. London) amused the meeting with some stories of curious verdicts and riders met with in his experience. One of these was the announcement of the foreman of the jury in a coroner's court that "death was due to the medical evidence!" In another case in which a man had been killed owing to the breaking of the axle of a vehicle, the jury recommended that the axles of all carts should be tested to breaking point! In a case of death which might have been due to lightning, but in which there were some circumstances pointing to the possibility of murder, the jury returned a verdict of "Death from a visitation of God under suspicious circumstances!" Dr. Smith said that it was sometimes the duty of the coroner to protect a medical witness from the unjust censure of the jury.

Mr. **FREKE PALMER**, as a solicitor practising in the police court, said that some medical witnesses, in his experience, were very fair and showed a readiness to help, but others seemed to resent any sort of challenge to their evidence by way of cross-examination. The importance of the evidence of a police surgeon was very great; the term was an unhappy one, because it seemed to imply that the police surgeon must give evidence on the side of the police, which was not the case. He complained a little of the shortness of time which police surgeons gave to the examination of persons alleged to be drunk, and of the fact that very often persons were not examined for illness.

Dr. **P. B. SPURGIN**, speaking as a police divisional surgeon, said that of late years, in his experience, stipendiary magistrates insisted upon a definite yea or nay to the question, "Was the man drunk?" and they would not allow the medical witness to qualify that in any shape or form. He described in detail the methods of examination which he carried out in cases of alleged drunkenness. The pupil reflexes and the smell of alcohol in the breath were absolutely useless as signs, but unsteadiness in gait, incoördination and thickness in speech went to make one consistent whole from which definite conclusions could be drawn.

The **PRESIDENT** briefly concluded the debate, when a vote of thanks to the openers, proposed by Colonel **T. H. OPENSHAW**, was unanimously carried.

HARVEIAN SOCIETY.

A MEETING of this Society was held on Nov. 13th in the Town Hall, Paddington, with Dr. **R. DUDFIELD**, the President, in the chair, when Dr. **N. D. BARDSWELL** opened a discussion on the

RESULTS OF SANATORIUM TREATMENT OF TUBERCULOSIS.

He explained that he would consider the sanatorium treatment of pulmonary tuberculosis only, and would give definite facts as to the mortality of cases after treatment. There were three important independent studies of mortality among sanatorium patients which gave results of striking similarity, an agreement which was presumptive evidence of their accuracy. These studies covered 3000 cases at the Adirondack Sanatorium in America from 1885 to 1911,[1] 1700 cases at King Edward VII. Sanatorium, Midhurst, from 1907 to 1914,[2] and 3738 cases at Brompton Hospital Sanatorium, Frimley, from 1905 to 1914.[3] In each investigation the patients were classified in the customary groups—early, moderately advanced, and advanced, and the mortality of each group during a period of some years subsequent to discharge was compared with the mortality of groups of the general population of corresponding age and sex. This method of comparing actual deaths with expected deaths was commonly employed by actuaries in mortality researches. The Adirondack patients belonged chiefly to the middle classes, the Midhurst patients to the middle classes of small means, and the Frimley patients to the so-called working classes. Speaking broadly, these figures showed that in "early" cases from these sanatoriums the mortality was six times that of the general population; in "moderately advanced" cases it was 16 times heavier, and in "advanced" cases 36 times heavier than that of the general population. These facts proved that the expectation of life of patients on discharge from a sanatorium fell far short of that of the general population. Less scientific but no less useful data were statistics of the percentage of patients alive on successive anniversaries of their discharge from a sanatorium. Dr. Bardswell's analysis of 10,000 cases treated by the public health authorities of London showed that of "early" cases 75 per cent. only were alive five or six years after leaving a sanatorium, and of moderately advanced cases 50 per cent. only survived a like period. Patients who survived the first five years had appreciably better prospects. Comparable records from Newcastle and Lancashire and Derbyshire sanatoriums, which dealt with patients of the more well-to-do classes, and from Frimley Sanatorium, which selected its cases on medical and social grounds and associated treatment with organised after-care, showed better ultimate results. In all statistics which allowed of the separate consideration of cases in which tubercle bacilli were and were not found in the sputum, a great difference was observed between the chances of survival of the two classes. In sputum negative cases after-history returns showed permanent recovery of 80 per cent. or more. If the sanatorium was judged by these cases the verdict was a flattering one. And although the criticism that many of such cases were not suffering from pulmonary tuberculosis was difficult to refute as mistakes in diagnosis certainly occurred, in Dr. Bardswell's opinion such errors were too infrequent to discredit the statistics. A more material point was our ignorance of the proportion of recoveries which sputum-negative cases would show without sanatorium treatment. Among "early" cases with tubercle bacilli in the sputum 70 per cent. or more made permanent recoveries after sanatorium treatment. Such cases formed only about 25 per cent. of the admissions to sanatoriums, a proportion which had remained constant for some years, in spite of greater attention to diagnosis. It was generally thought that every definitely tuberculous patient at some time represented the typical early case of the clinician, and should be recognised at that stage. Dr. Bardswell thought this untrue, and said that undoubtedly many cases were no longer "early" by the time the diagnosis was certain and the sputum positive. The "moderately advanced" cases comprised about 50 per cent. of those dealt with by public authorities, and were the best test for any system of treatment. In a sanatorium such cases almost invariably improved, and many lost all symptoms, giving most encouraging immediate results. But within five or six years of discharge 50 per cent. of them relapsed and died, unless they had incorporated in their lives the principles of healthy living taught them in the sanatorium. Thus, for working-class patients suffering from pulmonary tuberculosis, unless in the earliest stages, the sanatorium could not be regarded as an effective cure.

Duration of Treatment as a Factor.

The average length of sanatorium treatment, Dr. Bardswell said, was only about four months. Did anyone imagine that active tuberculosis could be arrested, much less cured, in that time? The surgeon did not; he demanded 12 months or longer for treating surgical tuberculosis. It could not be doubted that prolonged sanatorium treatment would give better results, as was shown by studying cases who continued to live in sanatoriums or on sanatorium principles. However, in many cases among the industrial classes habits and conditions were so bad that even two years' treatment could not render the patients proof against relapse on return, and for such cases four months' sanatorium treatment was as effective as 12 months' and more economical. Hence, sanatorium treatment should be divided into a short course of two or three months for purposes of education for all cases, and a prolonged course up to a year or more given with much more discrimination to selected cases, who showed promise of the will and the ability to take care of themselves after discharge. The difficulties of prolonged treatment were well known, but not insurmountable. Dr. Bardswell then summarised the situation by saying that we knew pretty well what the sanatorium could and could not do. It was the means of alleviating the lot of many and of returning a large number to a long life of usefulness. If pulmonary tuberculosis was regarded as one of the most difficult to cure of the curable diseases, this was no small achievement. Something better would, of course, be welcome, but at present sanatorium treatment and the surgical methods associated with it offered the best hope to the tuberculous patient. This hope was far from the forlorn character of that offered to patients before the sanatorium was introduced.

Laryngeal Tuberculosis.

Sir **StClair Thomson** said he would confine himself to sanatorium treatment for tuberculosis of the larynx. In his opinion there was nothing else and nothing better. Of his own cases he could trace less than a dozen which had recovered without sanatorium treatment, whereas he had had 119 cases at Midhurst Sanatorium alone where the larynx had cicatrised well, and with few exceptions remained so. In contrast to this he quoted some expert opinions written at the end of the last century. Morell Mackenzie in 1880 wrote: "The prognosis of laryngeal phthisis is always very unfavourable. It is not certain that any case has recovered." Other authorities expressed the same opinion: "There was never any expectation of cure. The appearance of tuberculosis of the larynx was the signal of death." The subject was of great importance, since it was calculated that to-day in England and Wales about 106,000 people suffered from laryngeal tuberculosis. It was certainly the commonest specific disease of the larynx. In his youth such patients were tortured with insufflations and antiseptic powders, and he was accustomed to see the larynx as a horrible septic cavity. Nowadays after a short time in a sanatorium the larynx cleaned up in a way he had never seen in the old days. In his opinion sanatorium treatment was the first necessity; the next was rest for the voice either by whispering or better by silence. Silence was difficult at home even for the richest, but was easy in a sanatorium with other silent patients and especially trained nurses. Sir StClair Thomson then showed a number of lantern slides, giving the statistical results of such treatment. In his experience the percentage of cases of pulmonary tuberculosis in which the larynx was affected was in early cases, 4·8 per cent.; in moderately advanced cases, 18·3 per cent.; in advanced cases, 31·5 per cent. Post-mortem figures at the Brompton Hospital gave the higher figures of 48 per cent. from 1908–11 and 34 per cent. from 1911–23. The average percentage of cures of laryngeal tuberculosis by the three methods of silence, whispering, and in selected cases the galvanocautery was 24·9 per cent., or 119 cures in 477 cases. Of the 74 cases selected for the cautery 62 per cent. were cured. These figures showed that there was no such thing as an easy case of laryngeal tuberculosis. All cases were serious enough to deserve a place in Group II. In reference to Dr. Bardswell's paper, Sir StClair Thomson said that the suggestion that if a case was sputum-negative it was not tuberculosis was absurd. Marked physical signs alone were quite sufficient evidence. He had himself seen a number of cases of laryngeal tuberculosis which had never had tubercle bacilli in the sputum. Many such cases had recovered at sanatoriums, but many others had waited for treatment till their sputum was positive and then died.

Early Detection Essential.

Dr. F. J. H. **Coutts** (Ministry of Health) said that the term sanatorium treatment had become almost synonymous with the residential treatment of tuberculosis irrespective of the type of institution, and was often applied to short courses of three months. In his opinion adequate sanatorium treatment had never been given to the working classes, and if it was tried the results would be as favourable as among the well-to-do. He recognised, however, that the circumstances of the worker often rendered it difficult for him to remain sufficiently long in the sanatorium. He agreed with Dr. Bardswell that neither the tuberculosis officer nor the doctor was always responsible for failure to find cases in the early stage, as very often the patients did not come for advice in time. The practice of some doctors in delaying notification until the sputum was positive was very unfortunate; it was most important to get patients while their sputum was still negative. With regard to the statistics given by Dr. Bardswell, we must not be discouraged if the expectation of life of sanatorium patients was below normal. Tuberculosis was a very serious disease, and patients who recovered from it could not expect to be as well as those who had never had it. The real question at issue was: Had a tuberculous patient a better chance of recovery with sanatorium treatment than without it? Statistics bearing on this question had been published and showed a marked advantage of sanatorium over home treatment. Dr. Coutts agreed with Dr. Bardswell that while it was valuable to give short educational courses of sanatorium treatment to as many patients as possible, prolonged courses should only be given to cases selected by the superintendents as likely to reap permanent benefit. But if the community wished to get the best possible results it should see that the conditions of life for discharged patients were such that it was possible for them to carry out sanatorium principles on return to their homes.

The Mental Effect of the Sanatorium.

Dr. W. C. **Fowler** (Superintendent, Pinewood Sanatorium) said that many of the most valuable results of sanatorium treatment were education and improvement of the patients' minds, especially in the better class. Among such results were the intelligent control of cough. Patients on arrival would indulge in much useless and harmful coughing, but after a few weeks would learn to restrain this and yet clear the lungs well by a few effective coughs morning and evening. Again, they acquired a certain philosophy of life which enabled them to accept their physical limitations and cultivate mental activities without violent physical exertion. They learnt to become practically non-infectious by the use of the sputum flask; they lost faith in milk and eggs and special diets, and learnt the fallacy of medicinal cures and the value of fresh air and a clean mouth. They grew to behave sensibly in hæmoptysis instead of being terrified, and finally they learnt from each other how to maintain cheerfulness and harmless recreations. Such results were invaluable, and could not be taught by the practitioner for lack of time.

Discussion.

Sir William Willcox said he could just remember the introduction of sanatorium treatment, and there was no question that it had revolutionised the tuberculosis problem. Nowadays both physicians and the public regarded it as a hopeful disease. Formerly the diagnosis of "consumption" was equivalent in the public mind to a death sentence. With regard to early diagnosis, he thought that one of the practitioner's greatest difficulties was that patients frequently waited too long before consulting a doctor. Another factor which had struck him as an examiner in medicine was the difficulty found by students in their five crowded years of study of learning the clinical signs of early phthisis. Many of them did not know how to percuss a chest, and some could not even percuss a heart. Percussion was a fine art, and too little respect was paid to it and to clinical signs owing to the modern tendency to rely on laboratory work and X rays. Another difficulty for the practitioner was delay in securing the admission of patients to a sanatorium. By the time patients finally reached a sanatorium they might have advanced from Class I. to Class II. This, of course, depended on the accommodation available, and it was doubtful if the nation ever could have really adequate sanatorium accommodation.

Dr. R. S. Walker (Tuberculosis Officer for Paddington) expressed his gratitude to speakers for excusing tuberculosis officers from blame for sending up advanced cases. In his experience the difficulty lay partly in patients seeking advice too late, and partly in their unwillingness to go to sanatoriums owing to the financial difficulty of providing for their families.

Dr. J. Thoresby Jones said that great progress had been made in the last 30 years in Paddington, and he thought the tuberculosis dispensary had done a great deal of good. His chief trouble was the difficulty of getting cases away in time.

Dr. A. Hope Gosse said he had studied a number of early cases and found that they had usually only just applied to a doctor, and therefore could not possibly have been diagnosed earlier. With regard to the difficulty of getting cases into sanatoriums, he had found very little delay in his experience at the Brompton Hospital, suitable patients securing admission to sanatoriums about three weeks after application. He had also had no difficulty in persuading them to go to sanatoriums, and thought that the hospital formed a most useful intermediate stage between the home and the sanatorium, where patients grew accustomed to the idea of treatment away from their relatives.

Dr. W. G. Bendle (Superintendent, Paddington Hospital) said he was accustomed to some delay in securing admission to sanatoriums, and thought improvement was desirable.

Dr. H. C. Phillips regretted the short duration of most sanatorium treatment, which appeared unavoidable owing to long waiting lists, but was most unfortunate, as patients returned to squalid surroundings improved but not fully cured, and so inevitably relapsed.

The President, after referring to reports Nos. 85 and 83 of the Medical Research Council, expressed his feeling of disappointment that the mortality of sanatorium patients after discharge was still much above that of the general public. In fact, no apparent progress had been made since sanatorium work began—possibly because sanatorium treatment had not been altered. He agreed with Dr. Bardswell that the treatment was not long enough, and that if surgical tuberculosis needed one and a half years so did phthisis. That was what we should select as our aim. With regard to delay in securing admission for patients, he had experienced very little, except in spring and summer when sanatoriums were fashionable. The real solution of the problem was the improvement of housing conditions. At present these were almost hopeless for tuberculous patients; the overcrowding was horrible, and as a result of it much of the money spent on sanatorium treatment was wasted.

Reply.

Dr. Bardswell, in reply, said that the situation would never improve until the social conditions and the life of the working classes were made better. With regard to delay in admission, that had been much reduced in the last two or three years, and did not now exceed two or three weeks for good cases. There was, however, a 20 per cent. seasonal flux which complicated the question. The duration of treatment could not be increased without causing an enormous waiting list, unless more money was spent and more beds provided.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A meeting of this Association was held at the Elizabeth Garrett Anderson Hospital on Nov. 11th, Miss M. Chadburn, the President, being in the chair. Dr. Morna Rawlins read a paper on

Complications of Gonorrhœa and Their Treatment.

She said that of all the complications of gonorrhœa she considered those of the uterine adnexa and the so-called gonococcal rheumatism were most to be dreaded. She believed that the tubes and ovaries were affected to a slight extent in a greater number of women infected with gonorrhœa than was generally realised. She proposed to confine her remarks to a few points in treatment. If the condition were seen before a pyosalpinx had developed the patient must be kept in bed and on a light diet, and long hot douches administered. It was immaterial what form of douche was used, although she herself preferred salt ʒii. to Oi. The douche must be slowly given, large in quantity, as hot as could comfortably be borne. The douches should be followed by the insertion of glycerine of ichthyol pessaries (10 per cent.). Hot fomentations to the abdomen might help to relieve pain. She had lately tried injections of sulfarsenol, recommended to her by Dr. C. Doble, with excellent results. The injections were given intramuscularly into the hip—e.g., beginning with 9 cg., increasing to 18 cg. or more daily for four or five days. Colonel L. W. Harrison had informed her that he found marked alleviation of pain following the use of diathermy, the temperature being 115° F. in the vagina and cervix. If operation had to be undertaken and both the tubes had to be removed, she urged that the uterus and the cervix also should be removed. If a conservative operation were decided on, it was her practice to blow through the tubes from the opened up abdominal ostia with a small pump.

Passing on to metastatic gonorrhœa, or so-called gonorrhœal rheumatism, she said that if a gonorrhœal case was seen early and treated effectively metastatic gonorrhœa should not occur. Joint or muscular conditions and also synovitis were usually accompanied by some cardiac disturbance which might become the most disturbing factor in the case. In all forms of metastatic gonorrhœa the treatment of the primary focus was of the utmost importance. In gonococcal arthritis Dr. Rawlins did not approve of splinting. Locally she applied lint soaked in ichthyol and glycerine over the painful part, and a pad of cotton-wool, and the whole was kept in place by a light bandage. If the patient slept better with a splint she allowed one for the night only and not for the day-time. Absolute immobility of the part, even in an acute condition, tended to favour ankylosis. The pain deterred the patient from harmful movements. Dr. Rawlins put these patients on a course of collosol manganese, 1 c.cm. intramuscularly daily, and the relief obtained by this and by heat applied locally was striking. When the temperature fell and the pain ceased the injections were stopped and massage and passive movements started. Vaccines should only be used with the greatest caution in joint cases after the acute condition had subsided. Salicylates were useless in gonorrhœal rheumatism. Collosol sulphur was useful given orally with meals.

Discussion.

Dr. **Edith Tindal-Robertson**, in her clinic, saw very few cases of established gonorrhœal arthritis, but many patients complained of pain round ankles and other joints; the pain appeared to be centred in the tendons and fibrous sheaths. Vaccines were useless; sulphur by the mouth seemed to cause improvement, but, on the whole, patient treatment of local symptoms appeared alone to alleviate these conditions. Another point to which she drew attention was the retroflexion often found in chronic cases, frequently associated with vaginal discharge. Sometimes the uterus was fixed, but more often lightly tethered. Surgeons were apt to refer back these cases for cure of discharge before attempting to correct the retroflexion, but in Dr. Tindal-Robertson's experience the discharge did not clear up until the uterus was placed in a position where free drainage was possible.

Dr. **Frances Huxley** said that in many chronic cases of adnexal infection the original infection had been insidious and the symptoms hardly noticed by the patient, but the tubes might, nevertheless, be blocked. She recommended medical treatment (unless there was a misplacement) if there was a chance of saving the tubes. Otherwise she practised removal of the whole tract. Salpingostomy was done in certain cases rather to encourage the patient than in the conviction that pregnancy was likely to ensue. Acute cases, if the differential diagnosis from appendicitis had been established, she also treated on medical lines.

Dr. **Eva White** differentiated medical diathermy, which aimed at producing heat without damage to tissues, from surgical diathermy which aimed at coagulation. The former was used with success in chronic gonorrhœa. The coccus was very susceptible to even a moderate degree of heat; probably 105° F. would kill it, and the tissues could be heated to 115° F. by diathermy. One electrode should be placed in the cervix, and the other in the urethra, in the rectum, or on the abdomen. The urethra was a useful site as a sensitive indicator of heat. Another use of diathermy was as general treatment to stimulate circulation and elimination so as to facilitate penetration of drugs exhibited by the mouth. The leucodescent lamp had proved very useful in her hands and appeared to be sedative.

Dr. **Agnes Savill** said that in intractable cases local ionisation of urethra and cervix had proved of great value. At St. Bartholomew's Hospital she understood that good results in tube cases and even in arthritic conditions were being obtained by means of diathermy.

Dr. **V. Russell** had recently treated four or five patients with tubal inflammation who had proved refractory to injections of collosol manganese with sulfarsenol (12 cg. intramuscularly) with most encouraging results.

Dr. **G. Sandes** described a case who had been treated for a considerable period in the out-patient department of the Lock Hospital, but had subsequently developed arthritis when actually in the hospital wards. She found that solid silver nitrate fused into a rod was very useful for infection of Skene's tubules. Sufferers from Bartholin abscess who could not lie up were conveniently treated by packing the cavity with narrow ribbon gauze impregnated with collosol silver; this seemed to prevent pockets.

Dr. **Louisa Martindale** asked whether Dr. Rawlins had ever tried surgical diathermy for gonorrhœal warts; she had found this very successful in a recent case.

Dr. **Dorothea Taylor** asked as to the relative value of films and cultures in the diagnosis of chronic cases.

Miss **Esther Rickards** had had success using succinate of mercury in these cases. She asked whether Dr. Rawlins approved of salpingotomy in the acute stage.

Miss **A. Bloomfield** asked (1) what was Dr. Rawlins's criterion of cure, and (2) which cases of vaginal discharge she treated as gonorrhœa. In the speaker's experience in not more than 1 in 20 patients could the gonococcus be detected; it was her custom to treat for gonorrhœa if pus was present in the urethra or cervix.

The **President** commented on the fact that many cases of acute gonorrhœa were cases of acute abdomen and exploration was necessary for diagnosis. She generally confined her treatment in these cases to washing out the tubes and draining Douglas's pouch by the vagina. It would be interesting to ascertain in how many cases where tubes were saved pregnancy eventuated. Of the many she had saved only two pregnancies were known to have resulted.

Reply.

Dr. **Rawlins** believed that diathermy had a great future in these cases, and in connexion with her clinic at Guy's Hospital she hoped soon to be able to give it an extensive trial. In answer to a question on the complement-fixation test, she herself had found it to be very satisfactory, but it was not manifest for six weeks at least after infection and did not become negative for about two months after vaccine treatment. She agreed that silver in any form was the most useful dressing for a Bartholin abscess. She treated gonorrhœal warts with the cautery, keeping the parts very dry, unless the warts were very numerous, in which case she cut off the heads with sharp curettes and then scraped off the stumps. Positive cultures and films were of great value; they were more likely to be positive if taken just after a period. If the pus stained very brightly and no other organisms were present the case was suggestive of gonorrhœa. Examination of the husband might help the decision. As to cure, six months' negative films and absence of pus was the ideal, but if only some slight degenerated pus was present, not brightly staining, the case was probably cured.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A clinical meeting of this Society was held on Nov. 6th, Dr. **G. M. Duncan**, the President, being in the chair.

Mr. **A. Mitchell** showed two children with *Spastic Paraplegia treated by Stöffel's Operation.* He pointed out that mild cases of deformity might be treated by continuous fixation followed by general rhythmic exercises, preferably to music, intermittent forcible passive movements and massage being forbidden as the spasticity was usually increased by these measures. More severe cases must be treated by operation with the aim of enabling the patients to walk. The main types of operation were three: resection of the posterior nerve-roots; section and suture of a main nerve-trunk—e.g., the sciatic; and resection of portions of certain motor nerves in order to restore the muscular balance—e.g., branches of the obturator nerve and the nerves to the gastrocnemius and the soleus, with occasional tenotomy of the adductors in addition. This third method had been employed in the cases shown, and both patients were now able to walk and to attend school.—In the discussion on these cases Mr. **W. Anderson** referred to the recent work in

Australia of Hunter and Royle, who advised division of the second, third, and fourth rami communicantes of the sympathetics. Mr. Anderson had seen four cases treated by this method, but thought them still rather spastic.

Dr. W. BROWN showed a child of 23 months with *Tuberculous Peritonitis, Dactylitis, and Lupus Verrucosus* (the abdominal condition had been treated by operation followed by mercurial inunction, and was now greatly improved); and a child of 14 weeks with congenital heart disease presenting unusual features. —Mr. F. K. SMITH referred to the rarity of tuberculous dactylitis in adults, and asked whether such cases generally died in childhood.—Dr. G. ROSE confirmed the rarity of this condition from his examination of all school-children of 13 years in Aberdeen for the last 15 years.—Dr. BROWN agreed, and said that in his experience such cases were almost always subjects of a multiple tuberculous infection and did not live long.

Mr. ANDREW FOWLER showed two cases of severe *Bilateral Dupuytren's Contracture* in adult males, treated by multiple subcutaneous fasciotomy under local anæsthesia.—In the discussion Mr. SMITH suggested that as the fingers were now extended the palmar fascia might be excised to prevent the possibility of recurrence.—Dr. H. R. SOUPER referred to a good result obtained by Gill's operation—excision of the palmar fascia through a transverse incision and the implantation of a fat-fascial graft.—Mr. ANDERSON, Mr. MITCHELL, and Dr. J. CRUICKSHANK raised the possibility of treatment by radium on the analogy of its success in cases of keloid.

Mr. F. K. SMITH read notes and showed skiagrams of two cases: First, a man of 51 with a *Tumour of the Upper End of the Femur and a Fracture of the Femoral Neck*, as the result of a slight accident in June, 1923. Tissue removed by exploratory operation at that time was reported "ossifying chondroma." Operation was not considered advisable, and the patient did not report again till recently, when definite changes for the worse were seen on skiagraphy. This case was discussed by several members, and the general impression was that the tumour had now taken on sarcomatous changes, and that radium was the only possible method of treatment. The second case was one of a girl of 17 with *Pyuria*, and some slight tenderness and enlargement of the right kidney; full examination by clinical and bacteriological methods, ureteral catheterisation and cystoscopy, X ray and pyelograms demonstrated irregular dilatation of the right ureter, a pyonephrotic right kidney, and calcareous deposits in the mesentery; and an oval calculus in the lower end of the left ureter, with dilatation and septic changes of the left kidney pelvis. Tuberculosis had not been demonstrated.—In the discussion of this case Mr. MITCHELL suggested lavage of the renal pelves.—Mr. SMITH, in reply, stated that his proposed treatment was to estimate the separate functional activity of each kidney by the administration of urea and ureteric catheterisation, to remove the calculus, and then treat on medical lines. In his opinion, if the case were tuberculous there would have been signs in the bladder or at the orifices of the ureters by the time the disease in the kidneys had reached its present stage.

ULSTER MEDICAL SOCIETY.

THE opening meeting of the present session was held in the Medical Institute, Belfast, on Nov. 6th, when Dr. J. SINGLETON DARLING (Lurgan), the new President, gave his inaugural address upon the

Organisation of Medical Services in Northern Ireland.

The address was looked forward to with interest, inasmuch as the Government of Northern Ireland recently appointed a Commission to consider the whole question of local government, including medical services, in Northern Ireland. Dr. Darling has been for many years active in all questions relating to medical politics, and his experience has been exceptionally wide.

Dr. Darling sketched the history of the Irish dispensary system, and was of the opinion that after 80 years' experience of this system there were now far larger numbers than were justified who continued to seek free treatment under the Medical Charities Acts. He was in favour of the extension of medical benefits under the Insurance Act or some other contributory plan, free from the taint of pauperism inherent in the present system, and held that reform on these lines, increasing the number of paying patients and diminishing the number of those who received free treatment, was more promising than a demand for the largely increased salaries which should be paid to dispensary medical officers if things remained as they are at present. Dispensary districts should be reduced in number, graded according to the services required, and remuneration should take account of the increased cost of medical education and of living and conveyance, since salaries were fixed 80 years ago. Opportunity should be made for the transference of dispensary officers from less to more desirable districts, according to merit and length of service. It was imperative that the issue of "lines" should be confined to really necessitous persons. Except in Belfast, he thought that workhouses should be abolished, as the Old Age Pension provided for the great majority of the infirm. Some of the existing workhouses might be utilised as refuges for the feeble-minded and harmless insane, or as almshouses, or as homes for a labour colony.

The Hospital System.

The present hospital system required reconstruction. It should be unified and administered under the county councils. A central hospital, fully equipped and adequately staffed, should be coördinated with as many satellite hospitals as the needs of the various populations might require. By such coördination those in charge of the smaller institutions could have the right to the services of the heads of the central hospital in consultation and their help in emergencies. The central hospital should be fully equipped, and include X ray and electrical, ophthalmic and dental departments, laboratories and pathological departments. Possession of one of the higher qualifications should be required for the officers of the central hospital, and the remuneration should be such as would attract the best type of men. Nurses should be trained at the central hospital and supplied to the affiliated institutions. Advantage should be taken of the existing hospitals, and in some counties the county infirmary would constitute a suitable central hospital. Necessitous patients should have the fullest provision for their treatment, while those able to pay should make a suitable contribution to the hospital, and the well-to-do should, in addition, pay the medical hospital reasonable fees.

Public Health Service.

There should be established, the speaker said, a properly constituted public health service under the county councils, who should have a full-time county medical officer, who would be the ultimate authority, and who would have the general oversight of the dispensary medical officers. It was a matter for consideration whether the tuberculosis service, child welfare, maternity benefit, school inspection, dental and ophthalmic dispensary should be administered under his direction. The boards of guardians should cease to have any connexion with the medical services. The county councils should have financial control, and function through committees, to which a number of outsiders representing the medical profession and the benevolent public should be coöpted. The existing nursing societies and cottage hospitals should be continued and should receive financial aid. The present methods of dealing with casuals would require a thorough overhaul, and a distinction made between the habitual and immoral casual on the one hand, and the decent industrial class, temporarily out of work, on the other hand.

Reviews and Notices of Books.

STUDIES IN HUMAN BIOLOGY.

By RAYMOND PEARL, Professor of Biometry and Vital Statistics in the School of Hygiene and Public Health and of Biology in the Medical School, Johns Hopkins University. Baltimore: Williams and Wilkins Company. 1924. Pp. 653. $8.

WITH the exception of three chapters these studies have already appeared in a wide variety of scientific journals during the last 20 years. As the author says, the only unity which can be claimed for them is in his point of view. Perhaps this is, as he suggests, the most significant kind of unity in a scientific book. In this case at least it guarantees a sustained interest to all readers who have a quantitative outlook on life. Particularly, we believe, will these essays appeal to the anthropologist. Dr. Pearl was among the first of the biologists to treat the animal man as proper material for laboratory study. His interest in this subject is never far away from any of the discussions, be they on the weight of the brain, the ratio of the sexes, vital indices, food waste and consumption, or the population problem. His contribution in the last field of a theoretical curve of population growth which fits all the actual curves derived from national statistics in 16 different countries is perhaps the most significant of all his researches. The diagram on p. 526 which shows on an arithlog grid the progress of the world's population compared with "the production of certain materials in the nineteenth century" is another astonishing example of the dramatic value of the statistical method. We may not derive from its study the same anxieties as assail Dr. Pearl, but nobody can look long at those curves of coal, and iron, and cotton climbing on a slope ten times steeper than man's own without being compelled to think. Is our civilisation doomed? If so, what will take its place? It is perhaps a mark of the true statistician, as compared with his more abundant counterfeit, that he uses his statistics to provoke argument rather than to quell it. A more provocative book than this collection of Dr. Pearl's work it would be difficult to imagine.

Under their motto "Sans tache" the publishers print a list of those of their employees whose skill and workmanship have gone to the making of the book. "The printing craftsman of to-day," they say, "is quite as much a craftsman as his predecessor. There is quite as much discrimination between poor work and good." Eight blurred pages in the copy sent to us suggest that the craftsman's vigilance is sometimes relaxed. On the whole the book is a creditable production, and the attempt of a modern large-scale manufacturing company to recover for the workers in their plant the just dignity of craftsmen is worthy not only of notice but of imitation.

INFECTIOUS DISEASES.

G. Jochmann's Lehrbuch der Infektionskrankheiten für Aerzte und Studierende. Second edition. Edited by Prof. C. HEGLER, with the assistance of Prof. B. NOCHT and Prof. E. PASCHEN. Berlin: Julius Springer. 1924. With 464 illustrations, for the most part in colour. Pp. 1077. $12.90.

THE first edition of this very complete account of the infectious diseases appeared in the autumn of 1914, and, no doubt owing to the war, does not seem to have reached this country. The author, Prof. Jochmann, lived long enough to see its success before he fell a victim to typhus, contracted, we believe, on a visit to one of the prisoner-of-war camps. His book is more comprehensive in its scope than its title might suggest. It includes diseases which in this country are usually relegated to treatises on tropical medicine, such as malaria, plague, and cholera. It contains an excellent section on the infections communicated from animals to man, and the various forms of food poisoning also receive ample consideration. Among the conditions which we are not yet quite accustomed to meet with in books on infectious diseases are rheumatic fever, herpes, and erythema nodosum. On the other hand, acute lobar pneumonia, which might be regarded as having a greater claim for inclusion, has been omitted. It is true that general pneumococcal infection is described in detail, as are also gonococcal and other septicæmias, including miliary tuberculosis. This section of the book, indeed, dealing with blood infections, is particularly full and instructive, and contains admirable articles on the enteric group of fevers, relapsing fever, and puerperal septicæmia. It is, however, not a little disconcerting to find general infection with the meningococcus or the anthrax bacillus discussed several hundred pages away from the more ordinary types of the diseases in question.

The production of this edition has been entrusted to the capable hands of Prof. C. Hegler, who has had the assistance of Profs. B. Nocht and E. Paschen. The book has been brought well up to date, and chapters on Weil's disease, herpes, and encephalitis have been added. As regards the latter, all the recent work on the identity of its virus with that of herpes is very fully discussed. The experience gained by the editor in the Near East during the war must have been of the greatest advantage to him in the revision of the articles on infectious diseases likely to be met with on military service. Dr. Jochmann believed that lengthy descriptions of various conditions can be considerably curtailed, or even dispensed with, provided that liberal use is made of illustrations and temperature charts. There are no less than 464 of these in the text, and almost without exception they are both instructive and conveniently placed. Those in colour are, on the whole, remarkably good, though it must be confessed that the exact shades of rashes seem often unattainable. Particularly successful are the illustrations showing cancrum oris, the Schulz-Charlton reaction, and the various septic and diphtheritic conditions of the throat. Dr. Jochmann was the first to prepare a serum for cerebro-spinal fever and to make use of intrathecal administration in that disease; from all points of view, epidemiological, pathological, or clinical, the article on this subject is a good one, but it is unfortunate that the temperature charts illustrating treatment should suggest that serum can be satisfactorily given at 48-hour intervals. The general opinion of authorities is that daily injections are necessary for at least four days, a procedure reserved by the author for severe cases.

The revision of the sections on variola, varicella, and vaccination, the latter especially good and well illustrated, has been undertaken by Prof. Paschen and gives but little ground for criticism. It is curious, however, that in the discussion on differential diagnosis in the chicken-pox chapter no stress is laid upon the distribution of the eruption. This omission is to some extent rectified in the corresponding section on small-pox, but even there the author is content to say that the one eruption is centrifugal and the other centripetal. It is evident that on the continent the views of the late Dr. Ricketts have not received the attention which they deserve, although his writings and those of Dr. W. McC. Wanklyn are mentioned in the short bibliography at the end of the chapter. The article on diphtheria maintains the same high standard as the others. It is interesting to compare the practice of different countries as regards serum dosage, and we note that Dr. Jochmann, while employing somewhat larger amounts of antitoxin than Dr. Baginsky of Berlin, is content with what are considered moderate doses in this country. He gives 3000–4000 units for mild cases, 4000–8000 for moderate, and 8000–9000 for severe, repeating next day if necessary. He approves of intravenous administration for the worst cases. His only indication for what we would consider large doses—e.g., 40,000 units or more—appears to be severe post-diphtheritic paralysis, which many of us would maintain is, when once established, not influenced by the use of serum at all. On the whole, the information given about the Schick reaction and immunisation is scanty and disappointing, and it appears that little work on the subject has been done in Germany. The editor, however, states that he has found difficulty in obtaining the literature relating to the extensive use of the test in America.

The book makes no pretensions to being a work of reference, and unusual and rare complications are often omitted. It appears to us better suited for the practitioner than the student, as it is unnecessarily large for the latter. Those especially concerned with fever work will find much to interest them, and can hardly fail to obtain some useful hints in treatment and diagnosis.

Drink Jottings.

By Maurice C. Hime, M.A., LL.D., Barrister-at-Law. Dublin: Hodges, Figgis & Co. 1924. Pp. 84. 1*s*.

We have previously reviewed two of Dr. Hime's books, "Wild Oats: A Sermon in Rhyme," in 1903, and "Schoolboys' Special Immorality" in 1899, and we commended their earnest and strongly-minded eloquence. Now, nearing the age of 84 and in retirement in County Donegal, Dr. Hime indefatigably continues his self-appointed task of preaching to the young, and he has collected several articles contributed to the local press and added some new chapters to form a little volume which preaches personal abstinence, and the national prohibition of alcohol as a beverage. Not even the most ardent "anti" could justly accuse the author of this contribution to the literature of prohibition of being a fanatic. His arguments are clear and decisive; he fastens on the weak spots in the anti-prohibitionists' armour. Why this tremendous propaganda against prohibition? Is it disinterested effort in the cause of so-called liberty? What is a moderate drinker? These are some of the questions which he raises directly or by implication, and the non-abstainer who fears that he will never be able to break his habit may take encouragement from the fact that Dr. Hime himself had taken no side in the controversy and had been a drinker of alcohol until a short time ago when, "better late than never," as he heads the chapter containing his "confession," he broke "so easily through a fifty-year-old habit" and took water for his dinner. Even those who disagree with the author will find this an interesting book.

Junior Red Cross Manuals.

British Red Cross Society. *Junior First-Aid Manual.* No. 1. By C. Max Page, D.S.O., M.B., M.S., F.R.C.S. Pp. 95. *Junior Nursing Manual.* No. 2. By Beatrice Agar. Pp. 103. *Junior Health Manual.* No. 3. By Beatrice Agar. Pp. 100. London: Cassell and Co., Ltd. 1924. 1*s*. 6*d*. each volume.

The Junior Red Cross is a movement which originated almost simultaneously eight years ago in Canada and Australia and is now world-wide in its extent. The Junior section of the British Red Cross is endeavouring as part of its programme to promote health among the school-children of this country, and it has recently produced three books along the lines of the well-known manuals of the "Senior" Red Cross Society. Mr. Max Page has dealt with the difficult task of presenting first-aid to children as a practical subject based on definite theoretical principles. The first section of his manual is devoted to an account of anatomy and physiology, written in a clear and lucid manner, and forms an admirable background to the second half of the volume, which deals very clearly with first-aid measures for the usual emergencies. The treatment advised is quite in accord with the changes in medical opinion which have taken place within recent years, and we fully agree with the statement of Sir George H. Makins, who has written a foreword to No. 1 of the series: Mr. Page "has produced a handy manual embracing succinctly the wide subject he has had to deal with." In No. 2 of this series the details of home nursing are described also with due regard to the theoretical aspect of the subject. The "good nurse" and her daily duties are dealt with in a restrained manner, and special chapters contain simple accounts of surgical nursing, the nursing of children, and bandaging. In the manual devoted to "Health," a more difficult task has faced the author, for good health must be presented to children as a positive virtue to be striven after and not as a dull and uninteresting alternative to disease. This book gets over a real difficulty effectively. Personal health, the healthy house, food and health, clothing, all receive attention, and there are also chapters on "A Healthy Baby" and "A Healthy Mind." That health is not purely an individual affair but one which concerns our neighbours as much as ourselves, is also insisted upon, and a chapter on "Public Health" has been wisely added. Each manual contains a suitable syllabus for lectures on the subject with which it deals, and these volumes will therefore prove useful both as text-books for members of the Junior Red Cross and other organisations for promoting health among children, and also as guides for those who have to give instruction in these subjects.

Physiological Principles in Treatment.

Fifth edition. By W. Langdon Brown, M.A., M.D. Cantab., F.R.C.P., Physician to St. Bartholomew's Hospital; Consulting Physician to the Metropolitan Hospital, &c. London: Baillière, Tindall and Cox. 1924. Pp. 511. 10*s*. 6*d*.

This is the second revised edition of Dr. Langdon Brown's book to appear since the war, and the new features which now appear should further increase its popularity. Two new chapters on the work of the liver and on asthma have been added, and new sections deal with insulin, uræmia, and fractional test-meals. It is somewhat surprising that the author in his chapter on the stomach makes no reference to the important physiological researches of A. J. Carlson, and his close adherence to the hormone theory of gastric secretion expressed on pages 49 and 61 appears to require some modification in view of recent work. Dr. Langdon Brown's learned pages are, as ever, enlivened by an epigrammatic pen, "The method of going about with a syringe full of insulin in one hand and a stick of barley sugar in the other carries its own condemnation with it," being one of many rewards for readers of this little book.

JOURNALS,

Quarterly Journal of Medicine.—The October number contains the following articles: The Effect of Iodine on Hyperthyroidism in Man, by S. J. Cowell and E. Mellanby. It has been shown that hyperplasia of the thyroid is always associated with a diminished iodine content in the gland, whether or not symptoms of hyperthyroidism are present. The relationship of the intake of iodine to metabolism in general has not yet been determined. The administration of iodine in minute doses in the form of cod-liver oil or of potassium iodide to patients suffering from exophthalmic goitre usually produces some alleviation of symptoms, whereas larger doses of iodides are almost invariably harmful. Eight cases of hyperthyroidism were treated by small doses of potassium iodide. They all showed signs of improvement, such as slowing of the pulse-rate, diminution of nervous excitability and a lowering of the basal metabolic rate. Treatment by iodides is therefore recommended as an adjunct to other forms of medical treatment in cases of hyperthyroidism and also as a preliminary measure to any surgical procedure.—A Clinical Study of van den Bergh's Test in Jaundice, by C. H. Andrewes. Observations are here recorded upon the value of the van den Bergh test which are based on a series of 184 cases. The author finds that the test enables a diagnosis to be made between a frankly hæmolytic and a frankly obstructive jaundice, but that it does not serve to differentiate icterus due to liver cell damage from other types of jaundice. The quantitative estimation of blood bilirubin allows the distinction to be drawn between a pernicious and a secondary anæmia.—The Relation between the Basal Metabolic Rate and the Pulse-pressure in Conditions of Disturbed Thyroid Function, by H. Whitridge Davies and John Eason. It was shown in 1922 by Read that the pulse-rate and pulse-pressure in cases of hyperthyroidism vary with the basal metabolic rate, and a formula was devised for calculating basal metabolism from these pulse records. The authors have made an extended series of observations on the pulse-pressure and basal metabolic rate in cases of hyperthyroidism. They find that an increase in the former is characteristic, whereas the pulse-pressure falls in uncomplicated hypothyroidism. The pulse-pressure and basal metabolism vary in the same direction, and determinations of the former afford a simple and reliable method of checking the accuracy of the latter.—Some Factors Concerned in the Ætiology of Tetany in Children, by Grace H. Anderson and Stanley Graham. A biochemical investigation was carried out on a series of cases of tetany in infants. The calcium content of the blood serum is always diminished in active tetany; in latent disease, however, it is not always lowered. Signs of tetany were found to disappear if acidosis be produced apart from any rise in the calcium content.—On the Pathology of Nephritis associated with Œdema, as illustrated by six cases, by S. C. Dyke. It has been suggested that in all cases of "primary chronic interstitial nephritis" there has been an antecedent but unnoticed attack of acute nephritis. The author records a series of six fatal cases of "chronic parenchymatous nephritis," all somewhat acute at the onset, which, he states, had not death intervened, might have conformed to the chronic interstitial type. Clinically they were all characterised by œdema, and histologically the kidneys showed degeneration of tubular epithelium, some glomerular changes, and deposition of cholesterol esters. Some of these cases showed a gradual retention of blood-urea. This is expressed as milligrammes per cent., which is, presumably, an error for milligrammes per 100 c.cm. It is suggested that those showing nitrogen retention would tend to pass into a state of secondarily contracted kidney. The relationship of an increase in blood cholesterol, the deposition of cholesterol-esters in the kidney, and the presence of œdema is also discussed. A series of three plates is included illustrating the microscopical appearances of the kidneys.—Spontaneous Subarachnoid Hæmorrhage, by C. P. Symonds. The article opens with a review of the literature dealing with spontaneous (non-traumatic) subarachnoid hæmorrhage. The possible ways by which blood may gain access to the subarachnoid space are discussed. The clinical manifestations of the disease are then described, and an account given of three new cases which have come under the author's observation. A brief description follows of the differential diagnosis and treatment. The article is illustrated by a coloured plate showing a small aneurysm situated at the bifurcation of the anterior cerebral artery which ruptured, causing subarachnoid hæmorrhage. The patient in whom this occurred was 24 years of age, the other cerebral vessels were healthy and no sign of disease was discovered elsewhere.—Cholesterol in the Blood in Cases of Gall-stones, by J. M. H. Campbell. Chauffard has warmly advocated the view that gall-stones owe their origin to a hypercholesteræmia, with consequent increased excretion of cholesterin in the bile, rather than to the presence of infection in the gall-bladder. Discordant opinions, however, prevail as to the amount of cholesterin in the blood in cholelithiasis. The author investigated 52 cases, and found that there is no increase in the amount of blood cholesterol in the presence of gall-stones, provided that the patient is not jaundiced. In some of the cases cholecystitis was actually present, which tends to overcome the possible objection to the value of the findings, on the ground that the observations might have been carried out at a time when active pathological changes leading to the production of gall-stones were over.

Reports and Analytical Records.

INNOXA.

(Les Laboratoires Innoxa, Agents, 15, Dover-street, London, W. 1.)

We have received an assortment of dermatological preparations with the common title Innoxa, consisting of a lotion, a cream, a *mousse*, and an unguent, with special directions for their employment rather as toilet preparations than as pharmaceutical substances. The formulæ have been suggested by Dr. Debat, late head of the Dermatological Laboratory of the Hospital St. Antoine in Paris, with the object of providing practitioners and dermatologists with toilet products which can be recommended with confidence. Innoxa Milk is made up on a basis of lanolin and cocoa-butter emulsion suspended in distilled rose-water. Innoxa Cold Cream contains in addition pure wax. Innoxa Powder with a basis of rice-starch, talc, and zinc oxide is intended to replace powders which tend to dry and irritate the skin. All the preparations are pleasant in substance and suitable for application in the methods which are indicated by their titles, while such perfume as they have is delicate and unobtrusive.

KALZANA.

(Therapeutic Products, Ltd., Napier House, 24/27 High Holborn, W.C. 1.)

In connexion with this preparation, a product of A. Wulfing and Co., of Amsterdam, a correspondent calls our attention to a misprint which we have already corrected, but as it appears to have caused some confusion in the minds of our readers it may be useful again to point out that the preparation is a double salt of calcium lactate and sodium lactate to which are added palatable adjuvants. Good reports have been received of its use as an addition to the diet of expectant and nursing mothers and of rapidly growing children, in the treatment of functional menorrhagia and in hæmorrhage, and all conditions where the promotion of calcium retention is indicated. It should prove a useful help to both physician and surgeon. As we before pointed out, to obtain the benefits of the drug for purposes of ordinary nutrition one or two tablets can be taken daily, but the same dose or three tablets can be taken three times a day where a special addition of lime to the diet is required. Children may take one or two tablets daily. They are best taken after meals either with a little water or milk or simply masticated. The preparation is put up in bottles of 90 tablets.

THE "STERAID" GAUZE CONTAINER.

(Robert Bailey and Son, Ltd., Marriot Street Mills, Stockport.)

We have received a sample of the "Steraid" series of absorbent and medicated gauzes packed in a patent dust-proof container which has considerable merit. The container consists of two cylindrical cardboard tubes enclosed at one end, which slide one within the other, thus forming a box. The dressing in a roll is contained in the inner cylinder and there is a slot running the length of both cylinders which, when in approximation, allows the dressing to be drawn out. By rotating the outer cylinder the outer slot passes over the inner slot and the dressing is enclosed in what is for practical purposes an air-tight compartment, while a reverse turn of the outer cylinder brings the dressing to view. The advantages of this arrangement are that the dressing is not exposed to light or air and is not handled, save that portion which is required for use. This invention is conducive to economy both of time and money, is simple to use, and certainly, from an hygienic point of view, should receive the attention of everyone who has to handle and use surgical dressings.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 22, 1924.

THE STATUS OF MIDWIFERY.

In times which many can remember the status of midwifery was thoroughly unsatisfactory. Medical students, it is roundly admitted, were educated only in the most desultory manner in the principles of the science and only by haphazard methods in the practice, while the various educational boards, the older universities defaulting as much as or more than the various corporations, did not press for a high standard from examinees; further, the general conduct of the clinical and domestic side of a superlatively important branch of medicine was not creditable to the practitioners, and obstetrics as carried on by midwives was an unregistered vocation. The last 50 years have seen a great change, and while at the beginning of this period progress along scientific lines and emancipation from ancient shackles took place but gradually, the days we now live in have seen remarkable improvements. They need not be enumerated for they jump to the eye. In the Lloyd Roberts Lecture, given in the opening pages of this issue, Dr. Herbert Spencer takes as his subject the Renaissance of Midwifery, and in a fascinating oration there will be found a history of the early phases of the science and art of midwifery, showing alike what scientific foundation the practitioners of post-Listerian days had to build on, and what ancient lore, tradition, or art they had to respect or discard. Anyone who reads this lecture and also a report, which appeared in The Lancet last week (p. 1011), of the interesting debate which took place on Nov. 6th at the Royal Society of Medicine, will have before him an illuminating picture of the fundamental revolution which has occurred within the last generation, and will see also what a number of problems, clinical, bacteriological, and administrative, remain for solution.

The debate at the Royal Society of Medicine, held between the appropriate Sections of that Society and the Society of Medical Officers of Health, had for its general subject the notification of puerperal sepsis, words which would have had no meaning for those to whom sepsis was an absolute mystery and prevention an undreamt of ideal—namely, the exponents of midwifery before the days of Lister and Semmelweiss. To-day the practice of midwifery means, above all things, the avoidance of sepsis, especially by the early recognition of abnormal conditions. Notification of puerperal sepsis, as Dr. J. S. Fairbairn pointed out in opening the discussion, becomes necessary when the first line of defence—prevention—has been breached; the next line of defence to be held being the early detection and elimination of disease, which is only possible if notification is employed generously towards suspicious cases. The immediate notification of all cases where legitimate doubt arises Dr. Fairbairn would allow to be difficult, if only because it would involve amendment of Acts of Parliament; but he made the valuable suggestion that obstetric consultations and bacteriological examinations might be arranged in local areas, and a certain amount of hospital accommodation for observation, nursing, and treatment be provided in connexion with such movements. This is a suggestion which, we hope, will bear fruit, for nothing would be more likely to improve the status of midwifery. If practitioners in any area had a centre where, upon voluntary notification of all cases of fever in childbed, scientific assistance and, in suitable cases, institutional help would be forthcoming, the advantages placed at the disposal of both patient and medical adviser would be difficult to exaggerate. In the debate which followed Dr. Fairbairn's opening the position of notification of puerperal fever, as it exists to-day, was severely criticised both on the grounds of its range of employment and its practical results, while the need for a better supervision of the midwife was insisted upon, though with due recognition that the Midwives Act had constituted a great advance. Of this there can be no doubt, but if, as Dr. R. A. Lyster contended, the level of midwifery practice could be substantially raised by efficient supervision and inspection, the value of more efficient notification would become immediately obvious. At the General Congress of Obstetrics and Gynæcology to be held next year at the Royal Society of Medicine, Dr. Russell Andrews will preside over a reunion of the various British and Irish societies devoted to the subjects of gynæcology and obstetrics, when one of the subjects set for discussion is the treatment of puerperal sepsis. To this discussion two whole sessions will be devoted, and it will be introduced by reports from two special committees in London and the North of England, when the grave interest of the matter will secure widespread attention for the conclusions of the congress. From all that has been written above it will be seen that now at least the medical profession is alive to the supreme importance of a scientific service of midwifery, and the status of work along all its lines is thereby indefinitely raised.

The importance of regular watch over pregnancy is implied in the Midwives Acts, 1902 and 1918, and the conditions in which medical help must be sent for by the registered midwife are set out in the rules framed by the Central Midwives Board; any improvement in the system of notification of puerperal fever would be in consonance with the whole meaning of the Acts. In all cases of illness of the patient or child or of any abnormality occurring during pregnancy, labour, or lying-in, the registered midwife must call to her assistance a registered medical practitioner, and the conditions referred to are broadly outlined in the rules of the Central Midwives Board. A large proportion of the midwifery practice of the country reaches the medical profession through the medium of the midwife, that proportion including, of course, most of the difficult and abnormal labours. We are publishing this week as a Special Supplement to The Lancet a treatise on the modern methods employed in the indicated circumstances, written by a group of well-known authorities. The various authors treat in this work of things as they are, in order that the advice given may be immediately useful; but the underlying lesson of the whole work is that things as they are too often represent things as they should not be, and as they will not be when the preventive side of midwifery comes more fully into realisation.

◆

THE HEALTH OF THE SCHOOL CHILD.[1]

The Annual Report of the Chief Medical Officer to the Board of Education for the year 1923, which makes its appearance this week, should be widely read by the public as well as by the medical profession, for unless, in addition to details concerning the prevalence of pathological conditions or the progress of sanitary developments, the general pattern of the school medical service is understood, public coöperation will not be intelligently directed. And the goodwill as well as the practical help of the public is necessary to-day in all the circumstances, preventive and curative, domestic and institutional, of any medical service. The Report deals with an interesting year, for during 1923 the restrictions following the need for national economy were becoming less stringent. Consequently authorities were permitted and even encouraged to consider certain extensions of their programmes where the wisdom of the proposed courses was obvious; and although the result of such increased activities as have occurred cannot yet be recorded, there is evidence in the Report that what was done in 1923, and is being done in 1924, will make satisfactory reading in subsequent documents. With a candour that is commendable in the head of a public service, Sir George Newman admits that the close scrutiny of the expenditure which was compulsory during the years immediately following the war, even while the limits imposed were vexatious, may have had a valuable influence; it has resulted probably in an increased attention to the matters where special economy could not be expected, and this has made for general efficiency.

---

[1] Annual Report of the Chief Medical Officer of the Board of Education for 1923. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2; or 120, George-street, Edinburgh; or through any bookseller. 1924. Pp. 194. 2*s*.

To the two main conditions affecting school health *en masse*—namely, the particular physical state of the children and their sanitary environment at school—Sir George Newman adds a third, for he speaks strongly of the moral influence that insanitation and unclean premises, defective light and insufficient ventilation have on the young. Not only do such things prejudice the health of the children, but they are deprived of the advantages of proper hygienic models and lose a valuable side of their training. There is no doubt that in many of the older schools, especially in country districts, the premises and furniture have declined from a tolerable health standard. This is a point which has often been quoted in our columns from the reports of school medical officers, and in Sir George Newman's Report it receives similar notice. Now when children have to spend their school hours in cold class-rooms, ill-lighted and wrongly ventilated, using unsuitable desks and unprovided with proper sanitary conveniences, the lessons to be learned from medical inspection become distorted, for the school itself may be a source, or at any rate the fomenter, of the mischief, the care of the officials being to some extent expended in the counteraction of mischief of official origin. It is of the first importance that medical inspection should be regular, thorough, and inclusive, and that common sources of defects should be ascertained; this should be followed by treatment, including as far as possible the provision of wholesome surroundings. During 1923 the specific requirements of the Board of Education as to medical inspection of children in elementary schools led to a routine medical inspection of 1,754,919 children, while a further 739,390 children were examined as specials, not being normally due for routine medical inspection, but recommended for the procedure by the school authorities upon the ground of particular physical or mental defect. There was a fall during the year in the number of children inspected as entrants, but this it appears can be attributed not only to leakage following on administrative defect, or—which is the same thing—a misunderstanding of official instructions, but also to the fall in the number of births registered in 1918–19. But one of the most satisfactory passages in the Report testifies to the steady and general increase in the number of parents who attend at the routine medical examinations, while refusal by the parents to permit their children to be medically inspected has dwindled to negligible proportions, and is to-day instigated almost always by a desire to conceal neglect. "Every year I am impressed," says Sir George Newman, "with the value and importance of the coöperation of teachers in the physical care of the school child," and everyone with experience as medical officer, as manager, or, as member of a care committee, knows that more than half the value of school inspections is due to coöperation between the parents and teachers in smoothing the way of the medical officer.

The findings of medical inspection for the year, so far as the figures allow them to be recorded, tell rather a sad tale at first sight, but closer consideration shows that the majority of the defects are such as do not endanger life, and do not even impair a general physique, though their neglect may lead to both these serious issues. A table based on the returns from London and 24 large representative areas shows the incidence in various groups of defects among 630,665 children of school age in 1923, when, as might be expected, by far the largest number of defects occur either under the heading of defective vision or under that of nose and throat disease, leaving dental troubles aside, the incidence of defect per thousand of the children inspected being 62 in the case of vision and 43 in the case of nose and throat. The early ascertainment of defective vision is now being fully promoted by school authorities, and to-day out of 317 local education authorities only 14 remain which make no provision for the diagnosis and correction of visual defects. Another table in the Report shows the enormous volume of work done by these authorities, but shows also that a considerable number of children recommended by the ophthalmologist for spectacles do not obtain them or do not wear them. There were, in fact, during 1923, 135,269 children who were ordered spectacles, while 15,238 failed to obtain them; this is a serious leakage. Teachers are here able to render valuable assistance to the school medical officer by encouraging children to use their glasses, and we may hope that the popular prejudice against the use of glasses will soon die out.

We hope to return to some of the many interesting questions in general and special pathology, as well as in administration, which this Report introduces, and in the meantime recommend its perusal to all our readers.

◆

MEASLES IN FRANCE.

Loss of life from measles is being closely scrutinised in France, where two apparently self-contradictory statements in regard to it are current:—

(1) Measles is less often fatal than scarlatina, or whooping-cough, or diphtheria.

(2) Measles alone accounts for more deaths than do scarlatina, whooping-cough, and diphtheria combined.

These propositions are certainly *not* true of this country in non-epidemic times, but the statistics and other data in support of them are worth quoting in extenso because they afford valuable clues to prevention and treatment. According to Dr. Ruggles George, of Toronto, the deaths from diphtheria in 1921 in the Canadian registration area numbered 1297. In the same period and area the deaths from scarlatina numbered 410, from whooping-cough 626, and from measles only 297. Again, in the United States registration area in 1921 the deaths from diphtheria numbered 15,683, from scarlatina 4718, from whooping-cough 8070, and from measles only 3790. Many other statistics could be quoted in support of the first statement as it appears above. In support of the second statement, it may be pointed out that during 1923 the death-rate per 100,000 persons in Paris was 0·3 for scarlatina, 0·6 for whooping-cough, 0·5 for diphtheria, and 1·6 for measles. In the *Annales de Médecine* for October there is a paper by Prof. R. Debré and Dr. P. Joannon, whose indictment of measles as a most malignant disease is supported by a wealth of statistical evidence. For example, in the period 1911–13 the annual mortality for every 10,000 infants under the age of 1 year in French towns with a population of more than 30,000 inhabitants was 31·4 from measles. The corresponding figure for whooping-cough was 20·2, and for scarlatina, whooping-cough, and diphtheria combined it was 25·9. It is probable that the actual mortality from measles is even higher than these figures would suggest, for when measles is unassociated with an eruption, the fatal capillary bronchitis or broncho-pneumonia to which it gives rise is liable to be notified as the primary cause of death. And when the comparative importance of diphtheria and measles as causes of deaths among hospital cases is studied, it is well to remember that the two diseases may coexist in the same patient and that diphtheria may not infrequently be given an unjust share of the blame.

Why, it may well be asked, is the comparative mortality from measles so much greater in France than in Canada, in large than in small French towns, and in the poor than in the rich quarters of Paris? This last-named difference is most striking. According to Prof. Debré and Dr. Joannon, the mortality from measles among children under the age of 6 years is four times greater in the three poorest than in the two richest arrondissements. And most of the few deaths in these rich quarters of the town occur in working-class families. As the authors point out, there are probably many factors accounting for these extraordinary differences which would at first sight suggest that we are dealing with two different diseases: one a rapidly fatal disease among slum children, the other a mild and transitory infection in children living in the country, the offspring of well-to-do parents. One factor no doubt is dominant: the slum child is more readily killed by measles than the country child because slum conditions favour development of the disease at an earlier age when the defences of the body are still very incomplete. It is significant in this connexion that of the 6266 deaths from measles in childhood in Paris in the period 1904–13 as many as 5132 occurred in children under the age of 3 years; there were only 488 deaths from measles among children over the age of 5. Another factor of sinister importance may be the hospitalisation of poor infants in Paris. Here, as elsewhere, there can be no doubt that measles is often contracted in hospitals to which infants and children have been brought for some other complaint. Again, the infant admitted to hospital for measles is liable to contract in hospital such diseases as diphtheria and whooping-cough, combinations with a very high mortality-rate. In connexion with the hospital problem there is also the delicate question as to the quality of the nursing and effectiveness of the isolation provided. These and other considerations bring us to another point: might it not be better to distribute the sick infants of the poor in small, carefully selected, and well-aired homes than in large creches where opportunities for infection are inevitably great? In this connexion Prof. Debré and Dr. Joannon point out that during 1922 as many as 37 of the 115 creches in the Paris area had to close on account of measles. Unless Schick and Dick testing and immunising come widely into vogue, the time may not be far distant when we may come to look back on the large hospitals for infants suffering from measles and other infectious diseases in the same light that we see the maternity hospitals belonging to the period when puerperal fever was an uncontrolled and uncontrollable disease.

Happily, however, there is a new factor calculated to arrest this flight of children from the hospital and to prevent our regarding it as a centre where the virus of measles becomes exceptionally malignant by frequent passage, massive infection, and secondary infections. This factor is the prophylaxis or abortion of measles by the injection of the serum of convalescents. It is many years since Nicolle and Conseil carried out their pioneer work in this field, in which the advances made during the past two years have proved most fruitful. In a paper by Dr. J. Paraf in the same number of *Annales de Médecine*, to which we have already referred, an account is given of the use for the past two years of this procedure, which has proved to be as innocuous as effective. In a children's ward he has never had a case of measles develop in spite of exposure to infection, and he has only one unfavourable comment to make on this treatment. The immunity conferred, sufficient though it may be to protect the child while in hospital, is so brief that it may be necessary to repeat an injection more than once during the same year. To get over this difficulty it has been suggested that the injections should be deferred till after the fifth day of the incubation period, so that instead of effecting a transitory passive immunity an attempt should be made to develop active immunity by modifying, but not completely aborting, the infection. Dr. Paraf does not express great enthusiasm for this procedure, which, while it may have a useful place in a large epidemic, adds to the immediate risks for the individual case, and which also is calculated to favour rather than prevent the spread of the infection to other persons. It is obvious, therefore, that the last word has not yet been spoken with regard to this procedure which is already extensively adopted in France, Germany, and the United States. But it promises to bring little short of a revolution in our conduct of hospitals for infants whom we have not hitherto been able to shield from one of the most infectious and deadly diseases of early childhood.

THE NEED FOR EXTENDED SICKNESS INSURANCE.

SPEAKING at a meeting of the Insurance Institute of London on Nov. 17th Lord Dawson emphasised the need for extended sickness insurance, especially among the middle classes. The present position in this country was, he said, that the rich on the one hand could provide for themselves, while the labouring classes were provided for by the National Health Insurance Acts. The middle-class family—that is, where the breadwinner's income did not exceed £1200 a year—was often cramped to a quite unjustifiable degree by the incidence of sickness. The growth of knowledge in medicine had brought with it increased cost in medical treatment, and to secure the very best that science could offer for the treatment of disease was becoming a burden too great for the middle-class home where the lives and prospects of the healthy members might be sacrificed to the consideration of one ailing relative. The solution of the problem, Lord Dawson thought, lay in providing the treatment of sickness outside the home, as was done in America and the Dominions, and if we were to avoid the pitfall of nationalisation of medicine, which would sweep away the most valuable factor in curative work—namely, the personal relationship between practitioner and patient, some adequate scheme of health insurance for the middle classes must be evolved. What was needed was organisation, and he thought that the lead for adequate medical treatment might be taken by local communities instituting health centres which would be available for their citizens on payment according to their capabilities. This had already been attempted by the city of Bath. Lord Dawson thought that the formation of health societies in local communities might go far to solve the big problem of administration and inspection to prevent abuses in such schemes. He was of the opinion that an insurance company—which was an institution run on business lines—might make an experiment with a well-thought-out scheme in some secluded local community. In discussing Lord Dawson's paper, Sir Alfred Watson pointed out the difficulty from the commercial point of view for an insurance company in fixing satisfactory premiums to secure the cost of medical benefits in a family; for the increasing cost, following continued medical improvements, opened up the possibility of future loss. But in some form or another we trust that Lord Dawson's suggestion may take concrete shape.

Annotations.

"Ne quid nimis."

SMOKE ABATEMENT.

THERE is general agreement that a smoke-polluted atmosphere not only interferes with the amenities of life but also affects the health of the community. In summarising the annual health reports of the various districts we have frequently drawn attention to the higher death-rates from respiratory diseases, when town is compared with country and when a dirty-aired town is compared with a clean-aired town. Estimates are put forward from time to time to show that most of the smoke pollution in industrial towns, perhaps two-thirds or three-quarters, is caused by domestic fires. It is somewhat difficult to reconcile these estimates with the smoke-palls and gloom of, say, the manufacturing towns of Lancashire and the West Riding as compared with the comparatively clean air of towns such as Derby, Leicester, Nottingham, and Swindon. But perhaps it is waste of time to endeavour to apportion the blame accurately between domestic and industrial smoke, for both are gross offenders. It is hardly questioned now that, except for a few metallurgical processes, industrial smoke is unnecessary. Chimneys serving boiler-furnaces where proper appliances and adequate plant are provided need not offend if due care is exercised by the stokers. Thus, with a trifling alteration in the law, industrial smoke might be a thing of the past if local authorities, stimulated by the Ministry of Health and backed by an enlightened public opinion, would but do their duty. At the recent conference in Manchester, promoted by the Smoke Abatement League, every phase of the question was discussed, and the proposition was laid down that in order to get the public to use a smokeless fuel the price of such fuel must not exceed that of coal. It was further shown that progress was being made towards the production of such a smokeless fuel for domestic use. Dr. H. Osborne, medical officer of health for Salford, makes a valuable contribution to the whole subject in his annual report for 1923. He emphasises the working man's liking for the cheerful blaze of the open fire, and states its advantages over the gas-fire on health grounds as a promoter of ventilation and a useful destructor for house refuse. His remedy for domestic smoke is therefore the prohibition of the burning of raw coal in open grates and the substitution of a smokeless fuel. One such product he has recently tested. It gave a beautiful glowing fire, burned away without any attention to a soft powdery ash, and gave off no smoke. He does not mention, however, how this fuel is likely to compare in price with raw coal. Dr. Osborne mentions the health value of the visible rays from an open fire, but presumably the gas fire would retain this value. Gas has the advantage over other fuels in its comparative freedom from sulphur products. He further states that the gas-fire is a poor ventilator, that there is a much larger proportion of carbonic oxide in its flue gases, and that the danger of down-draught bringing carbon monoxide into the room is considerable. We recognise that there is much carelessness in the fixing of gas fittings. They are frequently fixed without proper flues, and no adequate attention is given to the important matter of testing the gas fittings for leaks. Every gas company should in return for its monopoly have placed upon it the statutory obligation to test for leaks on request and in return for a reasonable fee. As was pointed out frequently in the recent conference at Manchester, the first step in securing cleaner air is to convince the public that domestic smoke is unnecessary, and that the air of our towns might be nearly as clean as the air of the country. When a powerful educated public opinion has been created, we feel sure that the competition between the producers of electricity, gas, and smokeless fuel will meet the demand.

RADIOGRAMS OF THE LUNG IN PNEUMONIA.

La Semana Medica gives, in a recent issue, what Dr. Carlos Hensen, the writer, probably with justice claims to be unique, a series of eight plates of the lung in an attack of acute lobar pneumonia. They were taken in a period of 12 days (the first apparently within a few hours of the initial rigor) at the patient's request, and they illustrate the condition as shown by X rays on the first, second, fourth, sixth, eighth, ninth, tenth, and twelfth days, but the exact date of the last is not given. They form a very interesting series, though not adding anything material to our knowledge of the pathology of the disease. Perhaps the most interesting point is the very considerable enlargement of the mediastinal glands, which shows after the lung has practically cleared up. This glandular enlargement does not reach its maximum till after the disease has begun to subside and is most prominent in the last picture of the series. The other point is that the consolidated area as seen extends well over to the right side of the vertebral column. This accords with the clinical fact that tubular breathing is so frequently heard along the paravertebral border of the unaffected side without implying any bilateral involvement. The series is worth studying, if only as illustrating the complete accord of the X ray and clinical findings, and is likely to remain unique owing to the rarity of the circumstances which would justify taking radiograms in acute pneumonia.

TUBERCULOSIS DISPENSARIES IN FRANCE.

THE high tuberculosis death-rate from which France has suffered for many years appears to be declining as a sequel if not a result of the well-directed impulse given to the anti-tuberculosis movement by the Rockefeller Foundation. The work of French organisations has also been remarkably successful in several instances, and an account published by Prof. P. Courmont in the *Journal de Médecine de Lyon* for October shows, among other things, how direct the relation may be between tuberculosis dispensary work on the one hand and the decline of the tuberculosis death-rate on the other. The first dispensary in Lyons was established in 1905 in coöperation with the Bacteriological Institute. After 1917 several new dispensaries were established, a total of seven being provided up to the present time. The functions of these dispensaries are much the same as those in this country; examinations are made and advice is given in the dispensary itself, whence visiting nurses, numbering 18, go to the patients' homes and help with advice and in other ways. The dispensaries also provide for disinfection of rooms, furniture, and clothing, help to transfer infants from infected to healthy homes, and keep in touch with the school medical service. Altogether there are more than 500 tuberculosis dispensaries in France, and if the results obtained by the dispensaries in Lyons are a true sample of the achievements of the French dispensaries as a whole, it is obvious that they are carrying out a most excellent work at an amazingly small cost. In 1923 the annual cost per patient treated by the dispensaries in Lyon was less than 100 francs. In the same period 2049 children were attended to, as many as 711 being sent to the country or to preventoriums. A total of 19,468 visits were paid by the nurses, 3040 families were visited, 3483 patients were treated, and 7000 persons were kept under observation.

Compulsory notification of tuberculosis not having yet been introduced into France, the notifications of the causes of death are the only means by which the incidence of this disease can be determined, and using this criterion, Prof. Courmont is able to publish some very interesting figures. In the period 1900–1905, the average annual mortality from tuberculosis in Lyons per 10,000 inhabitants was 35·4. In the five-year period 1919–1924 this figure had fallen to 22·7. It might be argued, as Prof. Courmont admits, that this decline depended on other factors than the dispensaries—i.e., on better housing and other economic conditions. To test the validity of this argument that the dispensary system is mainly responsible for this improvement, he has compared the decline in the tuberculosis mortality in the parts of Lyons provided with dispensaries with that in other parts without dispensaries. Lyons is a town with over half a million inhabitants, the Rhone cutting it into two approximately equal halves. In the four arrondissements on the right side of the river where, until 1921, there were only two dispensaries, the decline in the tuberculosis death-rate between 1905 and 1923 was only from 31·41 to 26·2. On the other hand, in the same period there was a decline from 38·45 to 19·7 in the overcrowded quarters on the left side of the river, where the work of the dispensaries had been most energetic. In one arrondissement in which, for various reasons, no dispensary could be established, the fall in the tuberculosis death-rate in the period under review was only from 36·9 to 30·6. The area in which the oldest dispensary was established showed a fall in this mortality in the same period from 41·4 to 18·2. Apart from the fact that the one arrondissement was supplied with a dispensary and the other not, there was nothing to distinguish the one from the other as far as health conditions were concerned. Figures such as these are convincing testimony to the value of the dispensary system.

LUMBAR HERNIA OF THE KIDNEY.

OWING to the extreme rarity of this condition we draw attention to a case recently published by Dr. Ciaccio,[1] of the University of Palermo, in which the diagnosis was proved by operative intervention. Hitherto the only case in which the content of a lumbar hernia was the kidney itself was described by Monro in 1803. J. Macready, in THE LANCET of November, 1890, gave a table of 25 cases of lumbar hernia, but in none of them was the kidney itself involved, and much confusion has also arisen by describing as lumbar herniæ certain traumatic conditions produced in the lumbar region as the result of wounds, or acute suppurative processes, or weak cicatrices. In cases of true lumbar hernia Grynfeltt and Lesshaft drew attention to the fact that they did not occur in Petit's inferior triangle bounded by the internal oblique and the posterior aponeurosis of the transversalis muscle, but in the "trigonum lumbale superius," which is a space below the twelfth rib when the latissimus dorsi is turned aside where the aponeurotic expansion of the transversalis is covered only by the latissimus. In the case now published, that of a female infant, a swelling about the size of a nut was noticed at birth in the right lumbar region, which gradually increased in size. When seen at the age of 18 months the swelling was the size of a lemon, rounded and well defined, smooth, elastic, but not fluctuating, and dull on percussion. It extended from the lower border of the eleventh rib to the iliac crest, and from the paravertebral line to the posterior axillary line prolonged. The swelling could be reduced but not completely, and without gurgling; when the child cried an impulse was imparted to it. Accurate examination failed to palpate the body of the twelfth rib; only a small bony nodule about the size of an almond could be felt. At the operation the swelling proved to be the kidney, normal in size but congested. It was easily reduced into the abdominal cavity, and the hernial canal was seen as a fibrous ring, oval in shape, with the long axis upright. During the process of closing this ring a small meningocele was discovered and removed. Recovery was complete and uneventful. This interesting and almost unique case, that of Monro being the only other described in which the hernial content was the kidney itself, points to the conclusion that lumbar hernia, like all herniæ in other regions without exception, is due to a defect in formation, and has its origin not in Petit's triangle, but in the superior costo-lumbo-abdominal triangle of Lesshaft, which is larger and offers less resistance. The real solution is to be found in a developmental error of the medullary groove. The vertebral arches as well as the muscles of the trunk originate from the same somites, and it is thus easy to understand that defects in the vertebral arches with spina bifida and meningocele, as well as defects in the conformation of the muscles of the back (in this case the oblique muscles and transversalis) have in common the same origin. And in Dr. Ciaccio's case, moreover, the absence of the twelfth rib, reduced to a mere bony stump near the transverse process of the twelfth dorsal vertebra, accounts for the defect in those muscles which are normally attached to it. In addition, the absence of the twelfth rib corresponded to some other important anomaly of development in one or more of the vertebral arches, anomalies which could not be ascertained precisely in detail, but which must certainly have existed as demonstrated by the meningocele met with during the operation.

THE SAFETY OF THE SCHICK TEST.

THE toxin-antitoxin test and the method of active immunisation which may succeed it appear to be free from danger in this country. No alarming or permanent ill-effects were produced in any one of the 2104 children and adults immunised recently in Edinburgh by the officers of the public health department, and Dr. W. T. Benson tells us[1] that he was able to obtain the consent of 42·3 per cent. of the parents of 6573 children under 10 at a group of Edinburgh board schools. Only four withdrawals of consent occurred after witnessing the effect of the first injection, and complaints from parents amounted in all only to 1·4 per cent. of the total number of children injected. The utmost inconvenience was a febrile reaction necessitating confinement to bed, mostly in the age-group 10 to 12. All the children recovered by the fourth day after the initial injection and suffered less from the later doses. The material used for immunisation was prepared by Dr. R. A. O'Brien and supplied from the laboratories of Messrs. Burroughs Wellcome. The safety of the method has thus not been in serious question. Unfortunately, this has not been so everywhere. In the early part of the present year 19 students at Concord Academy, Massachusetts, were rendered so ill by the Schick serum that they were obliged to remain in darkened rooms for three weeks. The toxin-antitoxin mixture used had passed the usual tests but, as was afterwards discovered, had been exposed to an unusually low temperature, below 0° F. in fact. Severe and prolonged freezing is sufficient to cause dissociation of toxin and antitoxin, with the result that the mixture becomes highly toxic. The occurrence naturally excited widespread alarm, but anxiety was allayed by the knowledge that its repetition could be prevented by avoidance of freezing. Our Vienna correspondent, however, sends us (see p. 1086) details of an occurrence in a children's hospital near Vienna of a far more terrible kind. A newly admitted infant developed diphtheria, whereupon seven other infants were injected with toxin-antitoxin mixture and promptly died of heart failure. No blame, it is stated, attaches to the medical officers of the hospitals, who followed precisely the directions given on the ampoules. The serum apparently was in order when bottled, but had been on hand for a prolonged period. It was supplied by what was at one time the State-controlled Serological Institute of Vienna, which is now a commercial undertaking. In Prof. Paltauf's time—he died early in the present year—the Institute was a model for other European centres of like nature, and a host of important publications have issued from it. The lesson is obvious. It is not safe to risk toxin and antitoxin becoming dissociated in the mixture by long keeping. Schick serum must be fresh. Experience of this kind is gained too dearly; precise and rigid control by responsible authority is required in the case of preparations so potent for good or for ill.

THE FUNCTION OF STATISTICAL METHOD.

THE Industrial Fatigue Research Board has issued, as No. 28 of their series of reports,[1] a lecture by Mr. Udny Yule on the Function of Statistical Method in Scientific Investigation. It would be hard to conceive of a more competent and more attractive expositor than the new President of the Royal Statistical Society, and his lecture deserves the widest possible audience. Mr. Yule points out that "statistical methods are methods for handling and elucidating the meaning of data affected by 'disturbing causes,' or generally by a multiplicity of causes. Hence their very wide applicability." It follows, of course, that the experimental method, which aims at the isolation of supposed "causes" and presumed "effects," will, the nearer it attains to its ideal, require fewer and simpler statistical methods. Indeed, in the case of perfect isolation, the only statistical problem to be solved is, What is the probability that this sample adequately specifies the characters of the "universe" from which it came? A question, however, which is not always easy to answer. This consideration may, perhaps, qualify Mr. Yule's moral: "Let the experimenter who is driven to use statistical methods not forget this, that the very fact that he is compelled to use statistical methods is a reflection on his experimental work. It shows that he has failed to attain the very object of experiment and exclude disturbing causes." Still, even if we accepted Mr. Yule's moral in its full rigour, the field of the statistician would remain immensely large, and the series of illustrations of method drawn from agriculture, biology, bacteriology, and industrial physiology, which he discusses, is a witness of that truth.

BACTERIOLOGY OF HUMAN MILK.

ATTRACTED by an observation upon a case of infantile gastro-enteritis, in which identical streptococci were isolated from the infant's stools and the mother's milk, Prof. L. S. Dudgeon and Dr. R. C. Jewesbury[2] have investigated the bacteriology and cytology of human milk in a large number of nursing women, and have also examined the influence of breast infection and mastitis upon the health of the child. Some of their conclusions are of considerable general importance and may be briefly summarised. They state emphatically that their results throw no doubt upon the unquestionable value of breast-feeding, but at the same time direct attention to this possible source of infection in breast-fed infants where the source is otherwise obscure. The commonest organisms found in the milk are staphylococci, as was pointed out by Cohn and Newmann in 1891, and many of these, including most of the albus variety, may be regarded as unavoidable contaminators: probably they exist saprophytically in the ampullæ of the larger ducts and, as suggested by the experiments of these observers, tend to pullulate in the intervals between suckling. Streptococci are also found in about 40 per cent. of cases, but there is little evidence that these are often of a pathogenic variety. A rather important series of observations was made upon the cytology of the milk and it was found that in some cases pus cells were present in large numbers, particularly in association with *Staphylococcus aureus*. Cases of this class appeared to be definite infective conditions of the breast and many of them subsequently proceeded to mastitis and abscess formation. From the stools of infants suckled by these mothers it was usual to recover the organisms found in the milk, and though there was often no evidence of harm accruing to the child it is obviously undesirable that these pyogenic cocci should obtain access to the infant's organism if this is preventable. The cytological examination of milk would appear to be a very informative procedure where breast infection is suspected, and often yields positive information of an impending mastitis before the clinical signs of this have developed. One interesting side issue may be quoted, that in human milk infected with staphylococci and *B. coli* no clotting occurs, such as is usual with cows' milk. This may perhaps go towards explaining the apparent general immunity from gastro-intestinal disorders of breast-fed infants consuming such highly-infected milks and their frequent occurrence in those fed on cows' milk which may be similarly infected.

THE PITUITARY PRINCIPLE.

IN the October number of the *Bulletin* of the Johns Hopkins Hospital Prof. J. J. Abel has given an account of his recent work in which he attempted to isolate the active principle of the posterior lobe of the pituitary body. As yet a pure crystalline compound has not been obtained, but the preparations have undoubtedly an extremely high order of activity; thus a striking contraction of the isolated uterus of a virgin guinea-pig is produced by a dilution of a "pituitary tartrate" so great as 1 part in 18,750 millions. Perhaps the chief interest of Abel's work is in the indication it gives of the intensity of the physiological activity of such a hormone as this; for it is not claimed that this tartrate is even approximately pure, and it may well be that the activity present is due to mere traces of the hormone clinging to the tartrate of an inert compound. Consequently the activity of the pure material, if ever it is isolated, may be such that it will act not only in the paltry dilution of 1 in 20,000 million, but also in dilutions of 1 in 1,000,000 million. Such considerations help to explain the failure of Abel and his colleagues on the one hand, and of H. W. Dudley, working in this country on the other, to achieve the final isolation of the pituitary active principle, and they make it likely that a considerable time must elapse before chemical methods will be sufficiently refined to bring success.

MEDICAL SCHOOL BUILDINGS.

MANY people find it easier to get a house to their mind by altering an old building rather than designing a new one from the bottom. And those who want to make the best of any of the princely benefactions that fall to medical schools nowadays have a great deal of anxious thought in designing their new buildings. The Rockefeller Foundation, most princely of benefactors, has now itself issued[1] a series of useful descriptions of a variety of recent buildings which have been put up, with some account of the methods of teaching in use in a number of them. Accounts, pictures, and plans are given of the new anatomy buildings at University College, London, Peking, Brussels, Würzburg, Basle, and New Haven, of the department of pharmacology at Yale, of the pathological institute at Graz, of the Boston Lying-in Hospital, of the department of obstetrics and gynæcology at Peking, and of the Thorndike Memorial Laboratory at Boston. The plans are clear and informative, and will be of real value to those who have the responsibility for erecting similar departments elsewhere. The volume is edited by Dr. R. M. Pearce, director of the division of medical education of the Rockefeller Foundation, and further instalments are promised as material becomes available. At the moment the two descriptions which will probably be of most interest to our readers are those of the Boston Lying-in Hospital and the Thorndike Memorial. The conviction that the teaching of practical midwifery is not as good as it should be is widespread, and better conditions in the maternity hospitals are beginning to be realised, notably in the new building at University College Hospital. The movement will no doubt spread and new equipment will be needed in many places. In the Thorndike Memorial is realised the combination of ward and laboratory, which is also one of the popular items in the reform of medical education and investigation. At present we try to achieve the combination by adding laboratories to the wards of general hospitals. It is a further step, and for some purposes an absolutely necessary one, to add wards specially reserved for investigation rather than the treatment of the sick poor to laboratories, and this new building in Boston suggests a convenient way of doing it.

The Services.

COLONIAL OFFICE.

THE Secretary of State for the Colonies has appointed Sir William Prout, C.M.G., O.B.E., M.B., C.M., late Lt.-Col., Royal Army Medical Corps, to be Senior Medical Adviser to the Colonial Office in London, in succession to Sir John Rose Bradford, K.C.M.G., C.B., M.D., F.R.S., who has resigned his appointment.

Mr. A. E. Horn, C.M.G., M.D., has been appointed Junior Medical Adviser, in succession to Sir William Prout.

COMMISSIONS IN ROYAL ARMY MEDICAL CORPS.

It is officially announced that not fewer than 20 commissions in the R.A.M.C. will be granted to successful candidates in an examination to be held in London on Jan. 28th next. Applications to compete must be made not later than Jan. 18th, and meantime a full statement of the duties and emoluments of the service can be had on written application to the Under Secretary of State (A.M.D.1), The War Office, Whitehall, London, S.W. 1.

ROYAL ARMY MEDICAL CORPS.

Capt. F. G. A. Smyth is granted the temp. rank of Maj. whilst empld. as a Dept. Asst. Dir. of Pathology.

Maj. R. F. M. Fawcett retires on ret. pay and is granted the rank of Lt.-Col.

ARMY DENTAL CORPS.

Lt. T. D. Corke to be Capt. (prov.).

RESERVE OF OFFICERS.

Supplementary Reserve.—Lt. C. W. Badger, late R.G.A., Spec. Res., to be Lt.

TERRITORIAL ARMY RESERVE.

Lt.-Col. A. M. H. Gray (Supernumerary for service with University of London O.T.C.), from the Active List, to be Lt.-Col.

THE FEES OF CIVILIAN MEDICAL PRACTITIONERS.

It is announced that the fee of 3*s.* 3*d.* authorised by the King's Regulations and Admiralty Instructions to be paid to civilian medical practitioners in respect of visits of ratings to the doctors' residences or surgeries for consultation will be reduced to 2*s.* 6*d.* as from Nov. 1st.

MEDICAL PRAYER UNION.—A meeting will be held, by kind invitation of Dr. Mary Scharlieb, at 149, Harley-street, W. 1, on Wednesday, Dec. 3rd, at 8 P.M. An address will be given by the Rev. R. Calder Gillie on Personality: God's Chosen Channel of Self-revelation. An intimation of intention to be present will be welcomed by the hon. secretary, Dr. Tom Jays, Livingstone College, Leyton, E. 10.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XCVII.

THE TREATMENT OF CLEFT PALATE.

MUCH has been written on the subject of cleft palates, and many variations of treatment advocated; nevertheless the end-results of treatment, as seen in middle-age in a large proportion of cases, are far from satisfactory from the points of view of speech and appearance. It is evident that more attention has been paid to the actual surgical closure of the cleft in early childhood than to the prospects of functional ability in later years.

Movements of the Soft Palate during Speech.—The action of the muscles which enter into the formation of the soft palate is to raise or lower the palate to enable it to make or break contact with the posterior wall of the pharynx so as to close off the oral from the nasal pharynx, and the functional success of the treatment is almost entirely dependent upon the restoration of this action. However successfully the cleft in the hard palate may be closed, unless a soft palate is obtained which will reach the posterior wall of the pharynx when raised and so enable the patient to shut off the oral from the nasal pharynx during speech, the result must be regarded as a surgical success but a functional failure.

Langenbeck and Lane Operations.—The usual operations performed in this country are variations of the Langenbeck and Lane operations, which have the common factor of the closure of the cleft by soft tissues, with the result that a certain amount of scar-tissue is formed. In view of the great contracting tendency of scar-tissue little wonder that after these operations the parts concerned tend to be drawn towards the centre-point of contraction—i.e., the middle of the palate. The dental arch is contracted with resultant loss of occlusion of the teeth, the pre-maxilla (in cases of double cleft) is drawn backwards with resultant marked facial deformity, and the delicate tissues of the soft palate are drawn forward, thus causing it to lose ability to perform its function of closing off the oral from the nasal pharynx, with resultant imperfect speech. Further evidence of this contraction may be obtained by X rays, when it will be observed that the two bony parts of the maxilla have so approximated that the original cleft appears only as a narrow dark area. These deformities appear more marked when the operation has been performed at an early age, as the bone is then more easily moulded than in later life. Another contributing factor to these deformities is the apparent lack of growth of the maxilla as a whole after surgical interference, which accentuates the condition as the mandible develops. Orthodontic treatment is often resorted to to expand the arch after these operations, but is usually not attended with satisfactory results, and it is open to doubt whether the extensive movement of the teeth that is required does not lead to their premature loss.

Preliminary Measures, including Operation for Hare-Lip.

The ideals to be aimed at in the successful treatment of these cases are: (1) The general health of the patient; (2) good speech; (3) proper mastication; and (4) good appearance. The technique to enable us to reach these ideals as far as possible is as follows. To enable the infant to take its food it should be provided at birth with a small sucking plate, which is of simple construction and can be made in one day. It will not always enable the infant to feed at the breast, depending largely upon the amount of milk present, but it will certainly enable the infant to suck from a bottle and feed like any normal child. This plate is only worn whilst the child is feeding, and may be continued without alteration until between the second and third months, at which time a hare-lip operation should be performed if necessary. The reasons for operating at this age are: (*a*) The child having been naturally fed for this period is better fitted to undergo the operation; (*b*) owing to the action of sucking, the two parts of the maxilla will have appreciably approximated, as may be demonstrated by a comparison of models of the mouth taken at birth and at this period; and this fact, together with the increased supply of soft tissues, renders the operation easier; (*c*) if the operation is postponed after the third month the child has a tendency to push its thumb into the cleft with resultant widening.

In cases of double cleft with a protruding pre-maxilla, it is essential for the future appearance of the child that the pre-maxilla should be replaced in its natural position between the two parts of the maxilla whilst the lip operation is being performed. After the hare-lip operation, the original sucking plate must be reconstructed or, preferably, a new one made, to conform with the altered conditions. This plate will carry the child on until the teeth begin to erupt, at which time the infant accommodates itself to the condition and will be able to feed without its assistance.

From the third month to the third year no special treatment is required, beyond special attention to the conservative treatment of the teeth. The dental arch not having been interfered with, the temporary teeth will erupt in good occlusion with the lowers except those involved in the actual cleft, which may erupt somewhat irregularly but call for no drastic treatment. The child will be able to feed quite normally, although the usual difficulty when starting with solid food may be slightly prolonged. This, however, is an entirely temporary trouble which is soon overcome and calls for no anxiety.

Definitive Measures Three Years after Birth or Later.

When the child reaches the age of 3 years there are three courses of treatment open, viz.: (1) Surgical, (2) prosthetic, and (3) surgical and prosthetic.

1. *Surgical.*—If it is desired to treat the case by purely surgical means the Langenbeck operation may be performed, but the hard palate should be closed first and followed later by the closure of the soft palate, as this course helps to lessen the pulling forward of the soft palate alluded to above. In theory this operation should give good results, but it must be realised that the soft palate is such a delicate organ that when part of it is lost by surgical interference it cannot be replaced by any means yet known to plastic surgery. If the operation is not entirely successful at the first attempt the resultant condition is far more difficult to treat, either by surgical or prosthetic means, than if the operation had not been performed. It is this great risk and the deplorable results that so often follow that preclude recommendation of this treatment, and compel us to seek a safer and more efficient treatment in which the risk is entirely eliminated.

2. *Prosthetic.*—The prosthetic line of treatment consists of the fitting of an obturator to restore the hard and soft palates. This treatment is commenced during the fourth year, and naturally the apparatus has to be renewed from time to time, depending largely upon the eruption of the teeth. The points in favour of this treatment are: (*a*) No operation having been performed upon the maxilla, except for the hare-lip, the dental arch develops like that of a normal child, with the result that the occlusion of the teeth is practically normal except in the immediate neighbourhood of the cleft in the alveolus; (*b*) as the result of the normal development of the maxilla unhindered by operation, the usual cleft palate disfigurement is avoided and the appearance of the child is not affected; (*c*) when the soft palate is not interfered with Nature endeavours to accommodate it to the condition; the two separate halves hypertrophy, together with the muscles of the posterior wall of the pharynx, and so facilitate the fitting of a really functional obturator. It has often been stated that if children are not operated upon or some appliance fitted at an early age they will develop bad speech and that this habit is very difficult to cure. This is a fallacy. Experience of about 300 cases has proved to me that the quickest and some of the best results in speech are obtained when the patient comes for treatment between the ages of 12 and 18, without any previous surgical or prosthetic treatment. The prosthetic treatment fulfils all the ideals mentioned above, good speech especially being almost a certainty. The only disadvantage of this treatment is that the patient has to keep in touch with a dental surgeon experienced in the construction of obturators.

3. *Surgical and Prosthetic.*—This combined treatment has for its purpose the closing of the soft palate by surgical means and of the hard palate by a dental plate.[1] The primary importance in speech of a functional soft palate is the basis of the treatment, and this is secured by utilising all the available soft tissue in its construction, thus leaving the cleft in the hard palate to be closed by means of a dental plate. This plate is of simple construction, and is similar to the ordinary denture which in a large number of cases is necessary to replace the involved incisor teeth, these being often irregular and requiring extraction. The advantageous features of this treatment are: (*a*) A long soft palate which reaches the posterior wall of the pharynx when elevated, resulting in good speech. Any tendency of the palate to move forward is obviated by the dental plate, which is carried slightly into the cleft. (*b*) A normal dental arch which has not been distorted by surgical interference, eliminating facial disfigurement and giving good occlusion of the teeth with normal masticatory function.

The best results from this treatment accrue when the operation is not undertaken until the child is 6 to 8 years old, and this postponement calls for patience on the part of the parents. It is often advisable to insert a small obturator after the age of 4 years to accustom the child to the wearing of a plate, to aid speech, and to give the parents the necessary assurance. In performing the operation special attention must be paid to the insertion of a dental plate at the same time, otherwise the soft palate will tend to be drawn forward and the most important feature of the operation missed.

Conclusion.

It must be borne in mind that if the early operation is not completely successful future treatment is far more difficult, and necessitates the use of more complicated appliances, than if the operation had not been performed in early infancy. It seems, therefore, desirable that the safer prosthetic, or the combined surgical and prosthetic courses, should be adopted.

ERITH AND DISTRICT NEW HOSPITAL.—The new hospital for Erith, Crayford, Belvedere, and Abbey Wood was opened by the Prince of Wales on Nov. 19th. The old hospital, which was built 50 years ago to meet the needs of a small riverside hamlet, contained only 12 beds, but as the needs of the district grew the arrangements of the institution became inadequate. In 1922, therefore, a new building scheme was proposed. A site at the top of Park-crescent was presented by Mr. G. H. Gunning, a small piece of adjoining land was purchased for £228, and a fund was started to build a new hospital at a cost of some £15,000. This hospital, which is now open, has 21 beds and is built on the most approved modern lines, including an operating theatre.

SURGICAL BOOTS.

BY CHARLES MACKAY, M.D., B.S. MELB.,
MAJOR, R.A.M.C. (HON.); MEDICAL OFFICER IN CHARGE OF ORTHOPÆDIC CLINICS, MINISTRY OF PENSIONS;

AND

D. DENHAM PINNOCK, F.R.C.S. ENG.,
ASSISTANT SURGEON, LONDON TEMPERANCE HOSPITAL AND VICTORIA HOSPITAL FOR CHILDREN; MEDICAL OFFICER IN CHARGE OF ORTHOPÆDIC CLINICS, MINISTRY OF PENSIONS.

THE ordering of surgical boots is not infrequently considered by the general practitioner to be the exclusive privilege of the orthopædic surgeon or of the so-called surgical bootmaker. This abdication of one of the realms of treatment is unnecessary in many cases, and in the latter instance may result in much harm to the patient. Practitioners risk the loss of both prestige and patient by sending a case of foot deformity to a surgical bootmaker for treatment. To us this is a confession of weakness. We consider that every practitioner should be able to order an ordinary surgical boot with knowledge of the therapeutic requirements, and of the effect likely to be produced.

There are many essential practical details of the actual making of a surgical boot which must necessarily be left to the skill and experience of the surgical bootmaker. The type of boot, however, should always be prescribed by the medical attendant, and whenever possible with the bootmaker present. We have come into close contact with many surgical bootmakers, and it is rare in our experience to find one who could be depended upon to supply a completely satisfactory surgical boot on his own initiative. The practice of patients going indiscriminately to surgical bootmakers is one to be strongly condemned. The majority of conscientious bootmakers would, we consider, greatly prefer a surgical prescription into which they could put all the skill and knowledge at their command. To be able to order surgical boots satisfactorily presupposes some orthopædic knowledge, but it is a comparatively simple matter, and in its main principles not difficult to comprehend.

This article is an attempt to formulate some definite principles to be followed in the ordering of surgical boots; also to submit a nomenclature which would enable a practitioner to write a prescription which should be easily understood and followed by a surgical bootmaker. These principles are the result of a considerable personal experience; but it must be remembered that this is notoriously a realm of treatment where differences of opinion are often acute and sharply defined.

In ordering surgical boots a primary consideration to be borne in mind is that of the patient's comfort; surgical boots must be comfortable or it is impossible to obtain any therapeutic advantage from them. As well as being comfortable, surgical boots must be efficient to correct the deformity, and fulfil the conditions required; we may often have the first without the second factor. A patient should never have to "break in" a pair of surgical boots, and although the full advantage of surgical alterations may not be realised for several months, these should never be so designed as to make too violent an immediate change in the attitude of the foot. Very often it is essential to accommodate our ideas of what is surgically necessary to what the patient can bear, and to hasten slowly.

Every prescription for surgical boots must be, in our opinion, to some extent a considered experiment, and we should be able to alter it as we would any other prescription, although not perhaps with the same degree of freedom. Patients should not be simply ordered surgical boots, and then seen again in 6 or 12 months' time. The patient should be seen as soon as possible after delivery of the boots, and again in about a month's time, when an examination of the feet and the boots will reveal whether comfort and efficiency are being obtained. With boots more than with anything else it is never wise to ignore the patient's feelings; if he is reasonably intelligent his remarks on the comfort or otherwise of his boots are well worth paying attention to. The sole of a worn boot will often yield much information to the observant eye.

The actual measuring for surgical boots by the bootmaker should be done whenever possible in the presence of the surgeon. Careful examination of the foot should be made, the type of surgical alteration to the boot decided upon, and then the measurement should be taken in a thick pair of socks or stockings. If the surgical boot is of a complicated character a fitting of the boot in an unfinished state should be made whenever this can be arranged—at this stage alterations can easily be made. In gross deformities a cast of the foot may be a necessary preliminary. For patients who cannot afford the expense of a hand-made surgical boot, surgical alterations of various kinds can be adapted to a strong machine-sewn boot, and this has often to be done.

The human foot, although in many ways a complicated structure, is in its essential mechanism a straightforward problem. The diagnosis of foot disorders of a bony or arthritic nature is always controllable by X ray examinations.

Ill-effects of Faulty Boots.

The modern system of encasing feet in stout leather boots with a comparatively narrow fore-part, ill-adapted to the shape of the foot, is the cause of much unnecessary suffering. Probably this and the wearing of badly fitting socks, &c., have been directly responsible for the greater number of the painful deformed feet seen. The narrow fore-part of ordinary boots, by squeezing the toes together, allows no freedom of movement, and in this way an atrophy of the small muscles of the foot is produced which leads to various deformities. Faulty footwear we consider is mainly responsible for such disabilities as hallux valgus, hallux rigidus, hammer-toes, claw-foot, various types of the so-called flat-foot, and metatarsalgia. This may seem to be a long list, but we have no reason to think that it is in any degree exaggerated.

It does not include such minor but painful conditions as bunions, corns, callosities, &c., and it must be remembered that several of these conditions may coexist in the same foot. For example, hallux valgus and rigidus are very frequently associated with some degree of flat-foot.

The Choice of a Boot.

The present-day orthopædic conception of a suitable man's boot is one which fits firmly round the heel, ankle, and instep, but gives the fore-part of the foot plenty of room. The boot should also be broad at the toes with a straight inner border, and the upper should be well raised to avoid pressure on the toes.

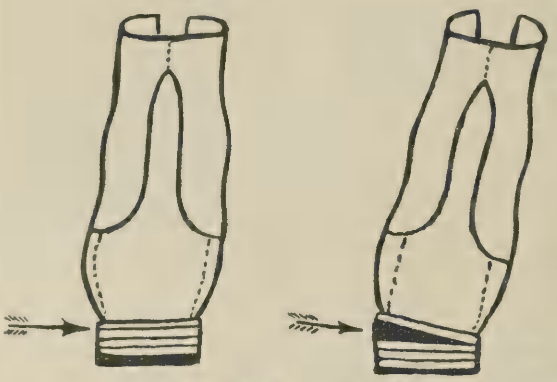
A point often neglected in choosing boots is the length. In walking and weight-bearing there is a forward thrust of the foot and toes which must have room for its accommodation. In boots made to measure the length is usually at least two sizes longer than the bare actual measurement. A short boot is a fatal mistake.

The Human Foot.

To simplify our mental picture of the human foot it is an easy matter to make a rough division of the bones of the foot into an anterior and a posterior portion; the posterior or hinder part of the foot consisting of the os calcis and astragalus, and the front part consisting of the remainder of the foot. The posterior portion of the foot is the firm support for the body-weight, and therefore requires to be well stabilised in the boot; it is not subject to many deformities or disabilities. The anterior portion of the foot is the mobile portion of the foot and comes into play in all active movements, games, &c., where lightness and quickness of movement are essential. Owing to this mobility it is necessarily subject to many stresses and strains. The ill-effects of these may necessitate the surgeon's interference, either operative or by the provision of surgical boots, or both.

From the foregoing it can be seen that surgical boots should fit firmly round the ankle and give stability to the posterior portion of the foot. They should also be so designed as to give as much freedom of movement as possible to the anterior portion.

FIG. 1.



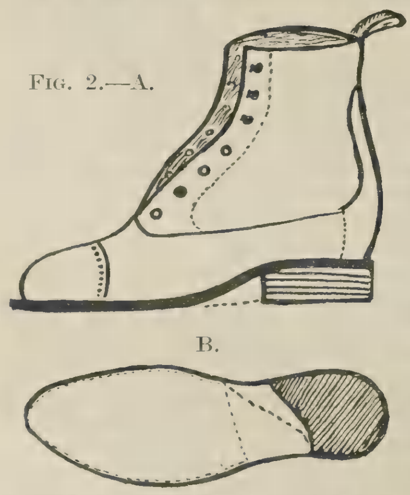
Heel wedge. Showing method of insertion.

Surgical Boots—Palliative and Remedial.

Surgical boots fall primarily into two large divisions. First, those designed to fit fixed deformities for the purpose of appearance, comfort, and relief of pain. Second, those designed with therapeutic purpose to combine comfort with an attempt at the correction of a non-fixed deformity, or to prevent the increase of a deformity if correction is impossible.

The first group may be called palliative only, and the second remedial or corrective. Under the first heading come the boots ordered for amputation of whole or part of the foot, rigid inversion or eversion, shortness of leg due to fracture with faulty union, and other permanent deformities, &c. Under the second come the cases where boots are ordered for temporary or remediable deformities due to paralysis or paresis, &c., which will improve under treatment.

FIG. 2.—A.

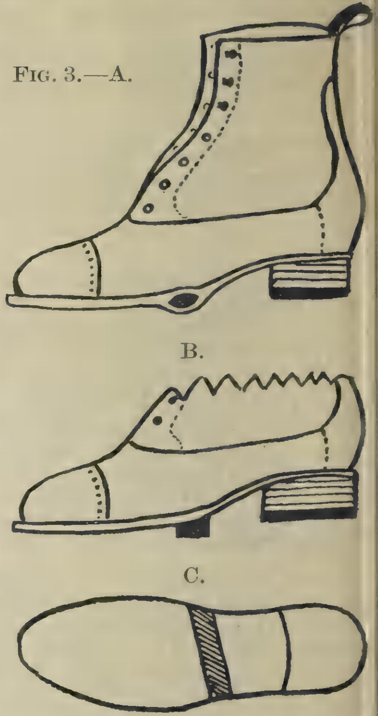


Oblique or crooked heel. (Dotted lines show position of continuous or "Thomas" heel.)

Surgical boots are hand-made, and necessarily require to be of first-class workmanship, hence their extra expense. Uppers should be of the best box calf or glacé kid; the lining may be either of leather, drill, or linen, as best befits the type of boot. Leather lining is inadvisable for cases of "hot" feet, as the excessive perspiration inevitably rots the leather more quickly than it would drill or linen. The occupation of the individual patient should be borne in mind when ordering the boots. The sole leather should be the best oak-tanned.

A boot consists of the upper with its lining, the toe-cap, the welt, the insole, the sole, the heel, and the tongue. In making the boot, the stiffener, a piece of thin but firm leather, is sewn between the upper leather and its lining; this goes round the heel as high as the seam and as far forward as the front of the heel. In surgical boots it is sometimes found necessary to prolong the stiffener on one or other side as far as the tread, or it may be produced upwards to grip the ankle. The factors which go to the making of a surgical boot, the measuring, the fitting of the special last, the cutting of patterns and linings, the closing of uppers, and the finishing of the boot, allow much scope for mistakes, as each process is technical and requires special skill and experience.

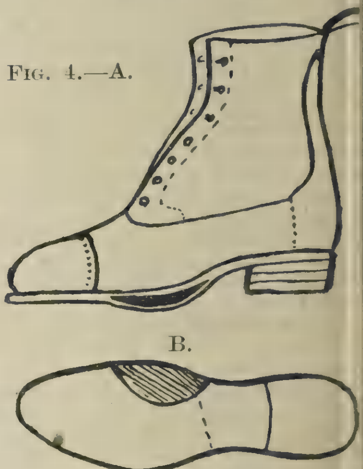
FIG. 3.—A.



Metatarsal bars. Showing position and two methods of fixing.

In serious abnormalities and deformities it may be necessary to take sketches of the foot in various positions or even to take a plaster cast. The surgical boot is necessarily built upon a special last.

FIG. 4.—A.



Sole patch or wedge.

Conditions Requiring Use of Surgical Boots.

Surgical boots or surgical alterations to a patient's own boots may be required for one or more of the following conditions:—

1. Shortness of leg.
2. Amputation of foot, Syme's or partial.
3. Amputation of toes.
4. Pott's fracture with eversion deformity of foot.
5. Fracture deformity of the foot itself.
6. Strains of the foot resulting in impairment of the inne longitudinal arch, different types of the condition classified as flat-foot.
7. Claw-foot or pes cavus.
8. Severe hammer-toes.
9. Hallux valgus and rigidus.
10. Metatarsalgia associated with partial loss of th transverse arch of the foot.
11. Painful conditions in the neighbourhood of the heel
12. Various forms of drop-foot.
13. Deformities associated with paralysis.
14. Congenital deformities.

The Prescription of Surgical Boots.

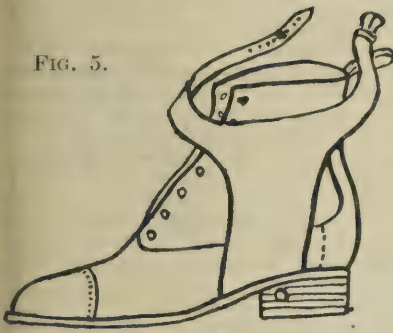
At this stage we will enumerate briefly the various special terms used in ordering surgical boots, and the disabilities to which they are applicable. The disabilities themselves will be dealt with separately and at greater length.

1. *Crooked heel* (Fig. 1).—"The heel of the boot is made ¼ inch higher on the inner side, tapering gradually to the outer side, so that the inner side of the heel is ⅓ inch higher than the outer. In addition the length of the heel should be extended forwards by about ¾ inch on the inner side." (This heel sometimes goes by the name of oblique heel.) This is the description given by Sir Robert Jones, but it is not always understood by surgical bootmakers that a crooked heel is a wedged heel, and it may be necessary to explain the term.

2. *Thomas or continuous heel* (Fig. 2) is similar to the former, but the extension is carried as far forward as the tread; this is not often found to be necessary.

3. *Metatarsal bar* (Fig. 3) is a bar of leather about ⅓ inch in thickness and 1 inch broad attached to the boot sole on its outer surface. The type most commonly found suitable is called a concealed metatarsal bar, and is incorporated between the sole and the insole. It lies obliquely across the sole of the boot from within, outwards and backwards, parallel to and immediately behind the heads of the metatarsals. By means of this bar the body-weight is directed more on to the necks of the metatarsals than on to their heads.

FIG. 5.

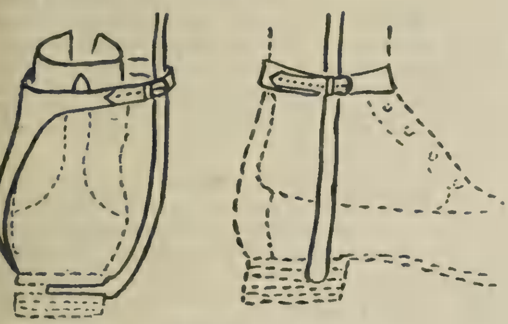


T-strap.

4. *Wedged sole* (Fig. 4) is a wedge-shaped piece of leather ¼-⅓ inch thick at base of the wedge, incorporated in the sole, usually on the inner side.

5. *Turned up or raised insole.*—This is a surgical alteration in which the insole is so cut that when sewn into the boot a part of it turns up to support the inner longitudinal arch of the foot, and is incorporated in the upper. In our opinion this is preferable to all the forms of metal support, &c. which are sold in such large numbers.

FIG. 6.



Surgical iron and T-strap.

6. *T-straps* (Figs. 5 and 6).—These are only of use with surgical irons, the inside T-strap with the outside iron, and vice versa. A T-strap consists of a piece of leather cut in the shape of a T, the vertical part being broad, some 2½ inches wide, and long enough to reach from the top of the boot heel to the malleolus, while the cross piece ends in a strap and buckle to fasten round the iron as a point of support. The purpose of this is to exert pressure on one or other malleolus to correct eversion or inversion as the case may be. Thus an *everted foot* requires an *outside iron and inside T-strap*, and vice versa.

7. *Cork insole* is the name given to the cork which is placed inside the boot to provide the amount of raising necessary to overcome the shortening of the leg.

8. *Cork forepart* is the cork used to fill the toe of the boot where the toes have been amputated, or in partial amputation of the foot.

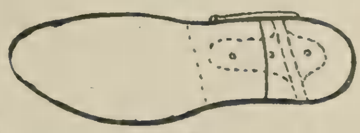
9. *Heel sockets.*—A properly constructed socket for the reception of the lower end of a surgical iron consists of a metal plate built into the heel and waist of the boot, to the under surface of which is welded the metal tube, which may be round or flat. If the former, it is called a *circular tube*, if the latter a *box socket* (Fig. 7).

10. *Sponge rubber*, which is made in sheets ½ inch thick, has recently come much into favour for the facing of a cork insole or a cork forepart, especially where the foot is tender and painful. Sponge rubber soles, half soles, or heels inside the boot may be ordered to give relief to tender feet.

11. *Metatarsal sock or pad.*—This is the name given to a leather insole made with a slight projection to fit the hollow of the foot behind the heads of the metatarsals. It brings pressure to bear at this point chiefly on the second, third, fourth metatarsals, and so tends to rest and support the anterior or transverse arch.

Generally speaking, when ordering surgical boots the quality of the leather should be stated, whether willow calf, box calf, glacé kid, &c.; also whether toe-caps are to be added, and whether the lacing should be to the toe-cap or to the toe; whether extra stiffening is required, or whether some ordinarily present round the heel should be left out. Other points include the question of the uppers, whether extra height is required; wedging of the sole or heel or both, and the height of the wedge; the placing of sockets in the heel for the reception of irons or caliper; the addition of a T-strap; crooking of the heel, usually in association with wedging; the addition of metatarsal bars; the raising of the heel or both heel and sole by means of (1) outside cork, (2) inside cork; incorporation of steel plate in the sole.

FIG. 7.



Box-socket.

In the subsequent article there will be considered the serious complication of shortening of the leg, as well as flat-foot, metatarsalgia, and other circumstances requiring surgical boots, constituting a general application of the principles here suggested.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

X Ray Treatment of Inoperable Tumours.

AT one of the recent meetings of the Vienna Medical Society two very instructive cases were shown where X ray treatment resulted in an unexpected improvement. In the first instance, Dr. Lenk showed a 11 year old girl, who had been operated on four years ago for a small spindle-celled sarcoma of the soft tissues of the trunk, attacking the bones. After an X ray treatment of six weeks she seemed "cured." Six months later a metastatic growth in the scar was again removed by X rays. In 1923 she returned in a most deplorable condition; she was cyanotic, dyspnœic, and had hæmoptysis. An X ray plate showed the lungs filled with small nodules. Under protracted radiation at long intervals she rallied, and the X ray plate now shows only a network of dark lines, where the multiple nodules had been situated (fibrous degeneration?). The girl is at present practically cured. The second case, shown by Prof. Schlesinger, was a woman who had been suffering for 12 months from symptoms of a tumour of the brain; vertigo, severe headache, vomiting, papillœdema. Multiple paralysis of the cranial nerves of a degree rarely observed soon appeared; all the nerves from the second to the twelfth on the left side were affected, while on the right side the third, the motor part of the fifth and the sixth were involved. The Wassermann was negative; antiluetic treatment was useless. Cerebral tumour was diagnosed, and as it seemed inoperable, X ray treatment was instituted. The effect was immediate; nearly all symptoms disappeared within three months, and the patient can now eat, masticate, walk, and move her eyes. The vomiting disappeared. In the discussion following the two demonstrations it was pointed out that quite a number of cases have already been recorded in which X rays were extremely effective in improving inoperable cases of tumours. Eiselsberg has reported seven cases and Szallitzer three cases, in which patients otherwise doomed to rapid death were saved. Redlich and Marburg have also seen such results, but they pointed out that it was not justifiable to speak of a cure. Both have seen cases improve, but they happened also to be present at the post mortem of patients, and in all cases the tumour was found to exist in the brain or medulla or hypophysis. Every operable case should be operated on as thoroughly as possible and afterwards subjected to radiation. Schwarz laid stress on the fact that the histological structure of the tumour was responsible for the outcome of the treatment. Gliomata were most subject to retrogressive changes under this kind of treatment.

Disastrous Diphtheria Prophylaxis.

Considerable public feeling was aroused recently in Vienna when it became known that a few weeks ago seven children, inmates of a children's hospital near Vienna, had died after receiving a prophylactic injection of anti-diphtheritic serum. The fact was at first kept secret, and it was only by accident that it leaked out. The public were seriously and justly annoyed at the attitude of the authorities, and the press did not abstain from calling this procedure by a hard name. The actual occurrence was as follows: A child, under treatment for some other ailment, contracted diphtheria and received its dose of antitoxin; seven other children, inmates of the same ward, were at once "immunised" by the usual method now used in many countries of injecting toxin-antitoxin. The result, however, was that all seven died, the chief symptoms being those of heart failure. The toxin-antitoxin mixture had been obtained from the Vienna Serological Institute, a former State institute, which has recently become a commercial undertaking. The ampoules of the mixture, as formerly issued by the State institute, were guaranteed as efficacious for a short period only, after which they could be exchanged free of charge, but the toxin-antitoxin as now issued by this institute was supposed to remain in good condition for two years. It is fairly certain that the original product had been tested when sent out, but it is well known that the antitoxin is liable to disintegrate much more quickly than the toxin, and so the unfortunate babies received actually a full dose of toxin, with rapidly fatal results. Inquiry showed that the medical staff of the hospital followed strictly the instructions on the ampoules, the correctness of which they had no reason to question.

A Dentists' Exhibition.

The union of the Vienna dentists intends to arrange an international meeting of dentists (medical men and mechano-dentists) in May, 1925, a prominent feature of which is to be an exhibition of all methods, apparatus, and appliances pertaining to operative and conservative dentistry. A large collection of specimens, wax models, and diagrams of diseases of the teeth is available. A special department will be devoted to the history of dentistry. The ancient methods of dealing with diseases and disorders of the teeth as revealed in Egyptian, Greek, and Roman findings and literature, will be shown either by means of original specimens or in good reproductions. The public will not be troubled with advertising elements, as the entire exhibits will appear as the result of coöperative work of the scientific union of dental mechanics.

Fatal Injuries at Football.

Within the last year several cases of severe collisions between football players have occurred in Vienna, of which one, occurring a few weeks ago, proved fatal. The young player had been accidentally kicked in his left side, collapsed, and was brought to the accident ward. A rupture of the spleen and fracture of several ribs was found, and in spite of an operation he died a fortnight later. Dr. Heslinger, from the Eiselsberg Clinic, recently reported on two other cases of severe injuries sustained by footballers as a result of such accidents, occurring within six months of each other. In both cases the victims were kicked in the abdomen and collapsed. In the hospital both patients were found to have sustained ruptures of the kidney, necessitating nephrectomy.

Death of Dr. Gersung.

One of the pioneers of surgery in Austria, Dr. Gersung, passed away recently at the age of 81 years. Although he was never on the teaching staff of the University, he succeeded in building up a world-wide reputation as a surgeon, and his methods of plastic operations and the cosmetic injections of paraffin, which he was the first to use, showed him to be an original thinker. He was an intimate friend of Billroth, and with his aid he organised the "Rudolf Stiftung," a special surgical hospital, which was the first on the continent to pay special attention to the training of nurses. Gersung's chief work lay in the improvement of methods of abdominal and limb surgery.

BUCHAREST.

(From our own Correspondent.)

Accidents with Salvarsan Preparations.

At the Interhospital Association meeting in Jassy held recently, Dr. Stefanescu discussed the causes, prevention, and treatment of immediate, early, and delayed undesired reactions to intensive arsenical treatment of syphilis. He emphasised that the cause might lie in the toxicity of the drug, the method of application, or the intolerance of the subject, or in all three combined. Treatment should be guided by the previous condition, the reactions to previous injections, by whether the disease was recent, was fully active, and whether there was any indication of a reaction on the part of the nervous system or viscera. The urine should be examined before every injection, and special caution was necessary if it contained bile pigments, albumin, or much sediment. The injection should always be made extremely slowly, watching for the least untoward sign. The physician should keep a full record of these cases, and a solution of epinephrin should always be at hand to combat any signs of intolerance, as advised by French syphilologists.

Hygiene of the Roumanian Railways.

At a recent meeting of the Sanitary Board of the State railways the executive officer was instructed to draw up certain rules and regulations regarding car sanitation, these to be considered in conference with various railway officials and reported on at the next regular meeting of the board. In carrying out the inquiry, four points were emphasised by the Sanitary Board—namely, sufficient amount of fresh air properly distributed, cleanliness of the car, including water closets, the proper heating of the car, and overcrowding. The Board also inquired whether the foregoing points had received sufficient consideration from the private companies owning railways in Roumania and the question was asked whether the Board should undertake to secure better sanitary conditions by formulating certain regulations. Circular letters have been sent out to a number of leading medical men and the character of the replies will influence the Board in its decision.

Prevention of Malaria in Albania and Montenegro.

A Bucharest medical journal reported recently on the sale and distribution of quinine in Albania and Montenegro as a prophylactic against malaria fever The chief medical superintendent in Albania accept the principle that quinine should not be distributed a public expense save in charitable dispensaries unless this measure is necessary to combat a severe epidemic of malaria. From past experience it is calculated that every 100,000 persons would require from 75–100 kg. (165–220 lb.) in such an emergency. As regards the distributing agency, he desires the hearty coöperation of every official, but for systematic distribution during a severe epidemic a non-official agency must necessarily be utilised, and in this matter the district boards are primarily responsible. Instructions are given for carrying out this systematic distribution of quinine. It is considered that, except in the case of a severe epidemic, the best method of making quinine readily acceptable is by the extension of the money-unit packet system.

Effect of Salt and Sugar on Diuresis.

Dr. Sadengeanu has repeated the experiments which were first made by Brunn in Germany for ascertaining the effect of common salt on diuresis. He remarks in an article in one of the Roumanian medical journals that with greater knowledge and better appreciation of factors outside the kidneys, which bear on secretion of urine, the problem of diuresis has become not only more complicated, but has also increased in importance both from the physiological and the pathological standpoint. As the result of his experiments he thinks we must modify our views in regard to the effect on diuresis of sodium chloride. His experimental subjects were given, in bed, one litre of water at 8 A.M. The urine was collected every half-hour until 12 o'clock, measured, tested for specific gravity, and the total amount of sodium chloride secreted during the four-hour period was determined. When one litre of tap water was given, more than the amount of fluid ingested was secreted in three hours. When distilled water was substituted, diuresis was not only not checked, but seemed rather more rapid. When 3 g. of sodium chloride were added, not quite the whole amount of fluid ingested was secreted in four hours. With 6 g. added, not more than eight-tenths of the fluid intake was secreted within the urine. With from 9–12 g. added, only 50 per cent. of the fluid ingested was secreted within four hours; with 24 g. only 33 per cent. In spite of the greatly increased sodium intake, the amount of sodium chloride secreted in the urine in the four-hour period was never much increased and was often decreased. With the addition of 12, 18, and 24 g. of sodium bicarbonate, diuresis was checked in much the same manner as by sodium chloride. The addition of sugar to water always caused an increase of diuresis; 100 g. of sugar to 1 litre of water produced 1660 c.cm. of urine in four hours.

SWITZERLAND.

(FROM OUR OWN CORRESPONDENT.)

A University Sanatorium.

ON Oct. 1st, 1922, a Swiss University Sanatorium (Sanatorium Universitaire) was opened at Leysin. The director and founder of this institution is Dr. Vauthier, who has advocated the idea for some years. In his first report covering the period from the opening till the end of 1923, he states that 46 students and professors have benefited by this institution. As far as is possible all the patients are engaged in some definite intellectual work, and Dr. Vauthier is well satisfied that such work at regular hours and in individually regulated amounts has never been unfavourable to any of the patients. On the contrary, it was found to have both a sedative and tonic action in giving the patients a saner and more balanced outlook and preserving them from the demoralisation of unemployment. The sanatorium has a good library of 2000 volumes, and in addition the patients have free access to the general library of Leysin which has 15,000 volumes. The sanatorium is regularly visited by professors of the different Swiss Universities, who usually make a stay of some days. During these visits they give lectures, and in private conversations they encourage the work of the sick students. With such resources the students of pure science, theology, law, and economy can make progress in their work. Students of applied sciences find enough theoretical work to keep them busy during 6 to 12 months. Medical students take the opportunity of studying tuberculosis, its diagnosis and treatment. They follow the courses of Dr. Rollier and his collaborators. Dr. Vauthier mentions that three of his patients have finished their theses, five are engaged in preparing theses, three have passed examinations after preliminary work in the sanatorium, and two have produced some special scientific work.

State Campaign against Tuberculosis.

The Bundesrat has lately demanded even wider financial credit for the needs of tuberculosis institutions and sanatoriums, although hitherto the astonishingly large expenditure of eight million Swiss francs (£320,000) per annum on these institutions has been covered by State loans. The following are the institutions, sanatoriums, and care centres which are subsidised by the State: 67 associations, leagues, and centres distribute yearly about one and a half million francs (£60,000) in anti-tuberculosis work. There are also 30 sanatoriums and preventive centres for adults, 21 sanatoriums and preventive centres for children, together with open-air schools, 55 pavilions and tuberculosis wards, including private children's hospitals. In connexion with these there has been opened, in the last few years, in addition to the University Sanatorium in Leysin, an institute for the study of tuberculosis and of physiology in high altitudes in Davos. This institute was founded by cantonal and local subscriptions, along with funds from various scientific societies and private generosity. Mention must also be made of the various care and help centres of the League for the Campaign against Tuberculosis in various cantons. These undertake to provide beds, clothing, provisions, and nursing equipment as well as money. This League also supports centres for advice and free medical inspection in a similar fashion to the welfare centres in England. The State proposes also in the next few years to further extend the subsidised "holiday colonies." This type of institution has been of great service, and statistics show that the children who spend their holidays in these colonies in the mountains require no medical attention for the next few years, and their powers of resisting infectious diseases are much increased. Another new institution is the Swiss Army Sanatorium at Novaggio, near Lugano, 644 metres above sea-level. This sanatorium is intended for convalescent tuberculous soldiers, no active tuberculosis being admitted. The sanatorium has 100 beds. The treatment consists in graduated regular work, chiefly agricultural. To the sanatorium are attached extensive farming grounds.

Criminal Abortion.

The question of criminal abortion is one which has been frequently discussed both amongst the profession and the public. In 1919, in the cantonal council of Basle, a Socialist amendment which demanded the abolition of punishment of criminal abortion was rejected by a small majority. The Swiss medical profession maintains in the majority that the unborn child must be protected by law. In one of its recent sessions the Medical Association of Zurich dealt at length with the subject. Two resolutions were passed. 1. Any practitioner who decides to induce artificial abortion is required to call in a colleague for consultation. The result of the consultation must be put down extensively in writing and such documents must be preserved by both practitioners for at least ten years. If for some reasons a second consultation is found necessary the statements made at the first consultation must be handed on to the second consultant. 2. In cases where medico-social or eugenic reasons play a part or when special difficulties arise it is recommended to consult a State-appointed health officer. In such cases the family or personal conditions of the mother ought to be thoroughly examined—e.g., by inquiry from the Poor-law authorities.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Paris Street Accidents.

WE who are used to the almost unchecked celerity of the French motorist even in the heart of Paris find the pace of the London taxi reminiscent of a slow-down cinema show, yet we have comparatively few accidents. Mr. Morain, Prefect of Police, has just come back from London, where he has been studying traffic problems, and where he has collected a tale of accidents that makes our flesh creep. He was told that during July, August, and September the London police had to attend to 22,351 street accidents, 196 of which were fatal. Paris, he says, does not produce such a list in a whole year. He admits, however, that Paris is susceptible of improvement in the matter of regulating its traffic, and he hopes shortly to introduce certain reforms such as removing railings where they are more obstructive than helpful, discouraging to the point of ultimate suppression the horse-drawn vehicle and hand-cart, providing better facilities for parking cars, improving the system of signalling to guide the traffic in the most congested areas, building subterranean and overhead passages, and discarding as far as possible the little sentry-box edifices which punctuate the open spaces of Paris with generous profusion. Doubtless these reforms will reduce our already low street accident rate, but we are still left wondering why our taxi rates and accident rates do not run parallel. Is it that the high speed of the Paris motor frightens the pedestrian off the middle of the street, making him take refuge on the inner half of the trottoir where a table and chair await him, or do the laws applying to street accidents discourage him from incurring them ? For the Parisian knows well that if he is run over in the middle of the street by a car he will be prosecuted for obstructing the traffic.

Thermal Cures for Poor Children.

Dr. Sersiron, of La Bourboule, pointed out at the recent congress of pædiatrists the value of the French thermal stations for the treatment of poor children, and in particular the stations of Auvergne. On his recommendation the congress supported the proposal to institute pavilions in some of the French stations, aided by private enterprise and public funds, with the object of securing for poor French and Belgian children such hydro-mineral treatment as might be required.

"Cancer Cures."

The Minister of Hygiene has recently lodged a complaint against certain medical institutes which promise by means of posters or advertisements the cure of cancer without operation. The Minister, who is President of the Franco-Anglo-American League against Cancer, is supported in his decision by the expressed opinion of the national and international congress of medical men, which is that the only chance of a cure in cancer is treatment at the outset either by surgical means, by excision, or by radium. He thinks that such advertisements which advocate medical treatment are dangerous in preventing early stages of cancer from obtaining adequate treatment. This measure has raised protestations in certain medical circles where it was thought that the doctor should remain free to look after his patients as he chooses, and according to his experience and his conscience. Such people also consider that there is no reason to limit initiative.

Preservation of Oysters by Super-Aeration.

In 1913 Dr. Gineste, of Bordeaux, proposed the super-aeration of oysters in order to purify them and preserve them, and recently Dr. Barbary, of Nice, Departmental Inspector of Hygiene, demonstrated to the Academy of Medicine the results of some experiments conducted under the Ministry of Hygiene. The experiments showed that super-aerated sea-water in specially constructed ponds was a medium in which healthy oysters could live free from all contamination and which, in addition, was a guarantee for the purity of the shell-fish. Dr. Barbary carried his experiments further and studied the action which super-aeration might have on pathological organisms existing in the molluscs. The oysters were sprinkled several times a day with water which contained more than 20,000 coli bacilli per litre and then they were transferred to the super-aeration ponds. The oysters got rid of the coli bacilli within six days when examined bacteriologically. It can therefore be concluded that oysters which have been contaminated by unclean water are mechanically cleaned and purified from pathogenic organisms at the end of six days. It is not a question of the destruction of the pathogenic organisms, but of their progressive removal by the mechanical effect of the aeration.

Doctors in Attendance at Theatre Performances.

There is a police decree, dating from 1908, according to which places of entertainment, catering for more than 800 persons at a time, must have a doctor in attendance. This decree has recently been challenged by theatre managers who have been wondering a little petulantly why such a precaution should be thrust on them, while it is not compulsory for train services and other undertakings which bring crowds together. The theatre managers' suggestion that doctors are superfluous on these occasions has been countered by the doctors themselves, who point out that in 1921 alone there were as many as 227 instances when the services of the doctor in attendance were required. These differences of opinion have recently been reviewed by the municipal authorities who are inclined to side with the theatre managers up to a certain point. It is suggested that instead of there being always a doctor on the spot, theatre managers should make arrangements with one or more doctors in the neighbourhood who would be prepared to come at once if summoned. In the case of evening performances there is already the excellent medical night service, an account of which has recently been given in THE LANCET. This service should, it is maintained, be sufficient to render the attendance of a doctor at every large theatre superfluous. The municipal authorities are also considering the advisability of theatres providing a first-aid outfit in the theatre premises.

A Ban on the Newspaper as a Food Wrapper.

Something of a flutter has recently been provoked in the Halles of Paris by the revival, from Oct. 1st of this year, of a decree dating back to 1912. This decree forbids the use of printed paper as a wrapping for the fruit and vegetables reaching the Halles. In a recent interview with the *Matin*, Mr. Montfort, President of the "Syndicat des Mandataires," has attempted to defend the use of the unsold newspaper as a wrapper for articles of food which must be cooked before it is eaten. This printed paper costs only from 30 to 50 fr. per 100 kilos, whereas new paper which has previously served no other purpose costs at least 150 fr. per 100 kilos, however inferior its quality. Were printed paper to be used for butter and similar foods, there might be some ground for protest, but Mr. Montfort can see no reason why the contact of printing ink with potatoes and carrots should be harmful, however evil may be the uses to which printing ink is put in other ways.

New Members of the Academy of Medicine.

At a recent meeting of the Academy of Medicine, in the section of Veterinary Medicine, Mr. Vallee was elected a titulary member in the vacancy caused by the death of a member. Mr. Vallee was formerly professor at the Veterinary School of Alfort, and is at present director of research in the Ministry of Agriculture. He is the author of several works on tuberculosis and foot-and-mouth disease. The new academician also invented, in collaboration with Mr. Leclainche, a serum against the infection of wounds. The Academy also elected, in the fifth division, two foreign correspondents — Sir John MacFadyean, of London, and Mr. de Jong, of Leiden.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table gives some of the principal health statistics for 1923 of four large towns, which are also shipping centres :—

Name of town.	Estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Resp. diseases with influenza.	Neonatal mortality.	Infant mortality.	Maternal mort. from childbirth.
Bristol	385,600	19·3	11·7	1·2	1·4	1·9	28	62	3·1
Newcastle-upon-Tyne.	283,800	22·4	12·9	1·5	1·1	2·2	38	98	4·1
Portsmouth ..	230,718*	21·1	10·9	1·0	1·2	1·6	24	52	3·6
Cardiff	226,200	22·3	12·0	1·6	1·1	2·1	30	74	4·6

* Civil population, on which the death-rates are calculated. The estimated civil and military population, on which the birth-rate is based, is 252,300.

Bristol.

Dr. D. S. Davies reports that the most encouraging feature of 1923 has been the success attending the work of the trained nurses employed either in the infant welfare and maternity department, or in the work of home inquiry into the causation of disease, the latter duty being now entrusted to three "home nurses." He also thinks that the Bristol and Clifton District Nurses' Society has good claims for municipal support. Dr. Davies quotes with approval the opinion of Dr. Charles V. Chapin (U.S.A.) that hitherto we have attached too much importance to the abatement of nuisances, to the comparative neglect of that class of work which carries advice into the home. The new houses erected during the year numbered 431, of which 88 were part of a municipal scheme. The report of the chief housing inspector shows that the position with regard to unfit houses is steadily becoming worse. There are hundreds of houses in Bristol, he says, which could be rendered fit by the provision of new roofs, floors, and windows, but few owners will face such expenditure. If these houses are allowed to become derelict, they will have to be replaced by new ones, which will cost £400 to £500 each, whereas an outlay of £100 to £150 would give them an additional 20 years' life. It is estimated that 1074 houses will be required annually for the next five years to overtake arrears, and until this is done slum houses and slum areas cannot be dealt with. Dr. Davies insists upon the importance of the provision of wholemeal bread for poor children who have not the advantage of a generous mixed diet. Owing to four fatalities caused by gas poisoning in connexion with bath geysers, the Bristol Gas Company have issued a memorandum to the public insisting upon the necessity for a flue being provided for every geyser, with effective means for the prevention of down-draught, and also for the need of a sufficient air supply to bath-rooms while the geyser is in use. Copies of the memorandum have been sent to the Bristol Master Plumbers' Association and the Association of Building Trades Employers. The Bristol Council has approved of an arrangement for the provision of 60 beds for surgical tuberculosis at the Treloar Home at Alton, and of 100 beds for early manifestations of tuberculosis in children at Frenchay, but both these schemes have been delayed by the Ministry on the plea of economy. The hours of bright sunshine in Bristol during 1923 were estimated to be 1386.

Newcastle.

Dr. Harold Kerr says 1923 will long be remembered for the enormous demands on public assistance rendered necessary by the distress. In spite of the vast expenditure on relief the year's hardships have left their mark on certain sections of the people. There is a sinister increase in the notifications of tuberculosis. Atmospheric pollution, which in recent years has been showing steady improvement, increased substantially in 1923. Since the beginning of July sunshine records have been kept at the Armstrong College, and only 513 hours of sunshine were recorded during the latter half of the year, to be compared with 725 at Cockle Park, a few miles north of Morpeth. The preliminary data in the cancer survey suggest that operative treatment is resorted to later in Newcastle than in other big cities. The occurrence of a case of small-pox in another district in the family of an assistant at a large Newcastle drapery establishment led to all the employees being vaccinated, and the example of this firm was followed by others. Mussels were suspected of causing a case of food poisoning, but the chief sources of the mussels eaten in Newcastle—namely, the Solway Firth and Holland—are certified to be safe, and bacterial examination did not indicate harmful contamination. The specialist services for the treatment of nose and ear discharges occurring as complications of scarlet fever at the fever hospital were continued with satisfactory results. The advantage of this early thorough treatment is incalculable, and lessens one of the well-known problems of education departments.

The attempt to get in touch with defaulting patients of the V.D. clinic by means of letters has been found impracticable, and has been reluctantly discontinued. There is a lack of hostel accommodation for girls and unmarried mothers infected with these diseases. During the last four years there has been a steady decline in the small number of infant deaths certified as due to syphilis. There has also been a decline during the same period in the notified cases of ophthalmia neonatorum. Of the 256 registered blind persons in Newcastle, 57 are said to have been blind from birth, but there is only one blind child under 5 years of age. Both measles and whooping-cough were rampant during the year, and counterbalanced the saving of infant life in other directions. There is much room for improvement in the attendance of expectant mothers at the antenatal sessions. Only 281 sought advice, while 6961 births were registered during the year. In the late autumn the Maternity Hospital which bears her name was opened by Princess Mary. When complete this institution will deal with every aspect of maternal and infant welfare. It is a voluntary institution containing 90 beds for patients, with accommodation for six medical students and 30 student midwives. Provision will also shortly be made for an up-to-date maternity and child welfare centre, an antenatal clinic and wards for wasting infants. Of the births in the city in 1923, 28 per cent. were attended by doctors, 36 per cent. by the maternity hospital, and 35 per cent. by midwives practising privately. Of the latter all but seven are certified by examination.

The pneumothorax method of treating pulmonary tuberculosis is used considerably both at Barrasford Sanatorium and at Walker Gate Hospital. Dr. C. G. R. Goodwin, the superintendent of Barrasford, states that this form of treatment is of very great value for a small proportion of the patients. It would be more useful still if it were possible to persuade the patients to undergo the treatment at an earlier stage of the disease. During 1923 the treatment was adopted in 22 cases out of about 200 patients at Barrasford. In the case of 11 the treatment failed to control symptoms, but in the other 11 the results were excellent. The new and efficient X ray plants recently installed at Barrasford and Walker Gate were of great value in controlling this treatment and also for diagnostic purposes. Dr. Goodwin emphasises the need for colony treatment after the sanatorium. He points out that the class of patients who receive permanent benefit at Papworth Colony are in the main similar to the class passing through Barrasford, but the cases from Barrasford too often return to bad conditions and relapse. He hopes that Newcastle-on-Tyne will give the lead to other municipalities and establish a colony.

The education committee has now established an open-air school for pre-tuberculous children on the corporation Pendower housing estate. Excepting for a small number of beds at Stannington Sanatorium the problem of surgical tuberculosis in children has not been tackled. A comprehensive scheme for a new abattoir with markets, &c., which is badly needed, is now under consideration. Dr. Kerr draws attention to the fact that the penalties imposed for the adulteration of milk are not such as will serve as deterrents. Rather better progress has been made in the conversions of pail closets and middens, but " there remain," says Dr. Kerr, " 4310 of these abominations in the city." Very many more houses are necessary to meet immediate needs. Overcrowding is the rule and subletting still rife, and one constantly comes across the most heartless cases of profiteering at the expense of the unfortunate tenants of so-called " furnished " lodgings. The committee has under consideration the question of appropriate by-laws for dealing with this question. Schemes for dealing with two unhealthy areas have been decided upon, and will be proceeded with when the housing committee has made provision for the dispossessed occupants.

Portsmouth.

Portsmouth may call itself happy with an infantile mortality-rate of 52 and a sunshine record of 1770 hours in a comparatively sunless year. Dr. A. Mearns Fraser informs us, however, that the housing difficulty still remains unsolved, and that the annual provision of new houses is still much below the normal. The health committee endeavoured to get an additional 100 houses for working people built on Portsdown Hill, and offered free sites to builders with roads and sewers already constructed. This represented a subsidy of £88 per house, but there was no response. During the present year a scheme more acceptable to the builders has been devised, and a tender for the 100 houses accepted. Towards the end of the year a tender was accepted for the erection of the first four blocks of flats on the Voller-street unhealthy area. Difficulties arose and the tender was withdrawn, but it is hoped that the blocks will be completed during 1924. The death-rate from pulmonary tuberculosis was the lowest on record. As is well known, Portsmouth has adopted the policy of recommending immediate self-disinfection after exposure to the risk of infection for the prevention of venereal diseases. It is difficult to estimate the effect of this policy, as no information is available as to men who have exposed themselves to the risk of infection, practised immediate self-disinfection and subsequently escaped disease. Of 97 male patients questioned at the V.D. clinic, only 16 had adopted self-disinfection within 10 minutes of exposure, 19 had practised some form of self-disinfection within one to three hours, and 14 at some later period still. Dr. Fraser favours propagandism as to the advantages of the early surgical treatment of cancer, and does not fear that such a campaign would give rise to cancer phobia.

The public analyst, Mr. R. P. Page, gives some particulars as to the testing of designated milks. From January to June, 27 informal samples were taken, out of which only 12 came up to the necessary standard. After this preliminary period formal samples were taken. Out of six samples of " certified " milk one failed to reach the standard, and all six were poor in fat. Thus one sample contained 3·3 per cent., two 3·2 per cent., one 3·15 per cent., one 3·1 per cent., and one 3·0 per cent. Of 13 samples of " Grade A " milk, all reached the standard as regards the number of bacteria, but five out of the 13 failed to secure the absence of *Bacillus coli* in 0·01 c.cm. Mr. Page compares these " Grade A " samples with ordinary milk supplied to local institutions. Of six samples of the latter only one reached the standard as regards the absence of *Bacillus coli*, and Mr. Page repeats the recommendation that hospitals and other municipal institutions should, in future, only accept tenders for " Grade A " milk, so as to create a greater demand for an improved milk-supply. His results " also show that the standard of 200,000 bacteria per c.cm. is vastly in excess of what a milk, produced under normally sanitary conditions, should contain."

Cardiff.

Dr. Ralph M. F. Picken points out that, while the death-rate from all causes has declined during the present century, the death-rate from pulmonary tuberculosis is rather higher during the second decade. A chart is submitted showing that the percentage of total deaths attributed to this cause has gradually increased during the present century from the neighbourhood of 18 to 19 to the neighbourhood of 21 to 22. Dr. Picken's investigation with regard to the effect of overcrowding and bad sleeping accommodation gives a negative result, and he expresses the view that the economic factor takes precedence of housing as the great predisposing cause of tuberculosis, and that the difficulty of securing adequate subsistence at the present time is the likeliest reason for the relatively increased part which tuberculosis is taking as a cause of death. With regard to venereal diseases the most urgent problem is the failure of a large proportion of innocently infected women to attend the clinic. The committee has therefore approved the principle of treating pregnant women, nursing mothers, and children at special clinics arranged under the maternity and child welfare scheme. The obstacles to the full development of antenatal work have been under consideration during the year. Hitherto there has been overlapping between the antenatal clinics of the committee and of the maternity hospital. Dr. Picken reports that a satisfactory scheme has now been evolved, by which a central antenatal clinic will be established at the maternity hospital, which will be conducted by the honorary medical staff of the hospital. The municipal maternity and child welfare officer, assisted by the health visitors, will be associated with the work of the clinic, and antenatal clinics will be opened on the outskirts of the city which will act as feeders to the central clinic. The corporation will accept responsibility for the maintenance in the hospital of Cardiff cases, recognised to be complicated, up to a cost of £2000 for the first year's working. Effective arrangements will be made for the interchange of reports between the antenatal clinics, the hospital, and the clinics for mothers and children. The clinics for mothers and children will be available for the teaching of students and pupil-midwives. The scheme is at present under the consideration of the Ministry of Health. The examination of milk samples indicates that an improvement is taking place. Thus, of 16 samples of ordinary commercial milk 62 per cent reached Grade A standard, as compared with 54 per cent. in 1922, and during the hot months 43 per cent. reached Grade A standard, as compared with 11 per cent. in 1922.

There has been some discussion in Cardiff as to the relative advantages of destructors and tipping. Dr Picken points out that by careful management most of the nuisances attributed to tips can be got over, and sums up : " I have no hesitation in saying that, in a place like Cardiff where there is so much land to be reclaimed, tipping is the best method, provided the tips are properly managed." In a special report to the Burial Board on cremation, Dr. Picken mention that there are religious objections to cremation on the part of Roman Catholics and Jews, who constitute about 15 per cent. of the population. The remaining 85 per cent. of the people are deterred partly by inherent conservatism, and partly by the increased cost and the necessity for certain legal formalities A table is given showing that the number of crema tions in Great Britain increased gradually from 341 in 1898 to 1023 in 1911, and to 2009 in 1922. It is obvious, says Dr. Picken, that the provision of a crematorium in Cardiff will not materially relieve the Board from the task of providing burial grounds in the near future. The open-air swimming ponds at Llandaff and Splott have been well patronised. The Llandaff pond, however, became very unsightly, and Dr. Picken considers that continuous filtration is necessary to make this pond the attraction and educative factor which it ought to be. Towards the end of the year a deputation visited certain large cities in connexion with the proposed reconstruction of Roath market and abattoir, and the city engineer has been asked to prepare plans based on the experience gained.

Dr. Picken does not think the extension of the city, which has added a population of about 20,000, has materially altered the housing problem. About 6000 (if possible 10,000) houses are needed during the decade 1921–31. Only 448 were built last year. Many instances of overcrowding come under notice, of which some examples are given. The record of bright sunshine for 1923, taken at Penylan, was 1555·5 hours.

MENTAL HOSPITALS SERVICE.

THE annual report for 1923 of the *Kent County Mental Hospitals* refers to the work of the two large institutions at *Barming Heath* and *Chartham Down*, accommodating 1700 and 1100 patients respectively. Both, unfortunately, are threatened with overcrowding; in this connexion an extraordinary discrepancy between the admissions in the two sexes at Barming Heath is worth noting, the numbers being 144 males and 236 females. In both hospitals there has been entire freedom from dysentery during the year, and in both success has attended efforts at granting patients more freedom; at Barming Heath 650 patients are in "open-door" wards, and many are allowed parole. The fact that these hospitals are not regarded as "prisons" is evidenced by several applications for voluntary admission, which, of course, in the present state of the law, have to be refused. There are several curious discrepancies not easily understood when it is remembered that these two hospitals are controlled by a single committee. For example, Barming Heath possesses an occupational teacher, and a "sister tutor," whose efforts have been rewarded by a very creditable number of successes in the nurses' examinations; at Chartham there are no such officers, nor are there facilities for giving continuous baths, such as have been installed at Barming Heath. Chartham, however, has the advantage in two respects—namely, in the provision of ward letter-boxes and of night-dresses for the women, neither of which amenities have yet been introduced in the sister institution. If these things are necessary in one hospital, they must surely be so in the other. The visiting Commissioners to Barming Heath also suggest the provision, when feasible, of an additional medical officer, a clinical laboratory, a nurses' home, verandahs, and a clinical room for interviews with patients. In this hospital the practice of staffing male wards with female nurses is being extended, and an enterprising spirit is shown in the fact that "arrangements have been made for special leave to be given to selected nurses in order that they may undergo training in a general hospital." The Christmas service in the chapel of this hospital was attended by no less than 500 of the general public, who subsequently visited the wards; the extension of this excellent practice might well lead to a better understanding by the public of the work of the mental hospitals.

Certain recommendations are made by the visiting Commissioner in the annual report of the *Devon Mental Hospital*, of which a number have already been carried out, the visit in question having taken place early in the year. He suggests the provision of an operating-theatre (the plans for this have now been drawn), ward letter-boxes, and improved sanitary arrangements (these have since been provided), and a more varied dietary, to which attention has also been paid. He also criticises the practice of sending patients out on trial without money allowances, and the provision to the wards of large stock bottles of aperients, to be administered at the discretion of the nurses and attendants. Tuberculosis appears to be unduly prevalent in the hospital, the deaths per 1000 from this disease numbering 26, as against 11·8 for all mental hospitals. Efforts are being made to grant as much freedom to the patients as possible, and these have been attended with success, but a type of difficulty sometimes encountered is illustrated by the case of "a man who has made no less than three attempts at escape since being sent here from Exeter prison 22 years ago. He is of the moral imbecile type, for which nothing but strict discipline is of any avail, and who will always take liberties whenever vigilance is relaxed. It is this class of case which will always hinder the development of the hospital atmosphere if sent to these institutions, and I hope the time is not far distant when some other provision can be made for them. The fact that they come from prison also adds to the stigma which still attaches to mental hospitals, and which it is our earnest endeavour to remove." The report of the recently appointed medical superintendent, Dr. Richard Eager, contains an account of numerous changes in the organisation of the hospital making for efficiency and economy; this should be of considerable interest to the authorities of other such institutions. The introduction of daily diet-sheets, for example, has resulted in the saving of 7140 ordinary diets, which would otherwise have been issued for patients unable to partake of them. The issue of bedding and clothing from the laundry in immediate exchange for soiled articles, stocks being kept there instead of in the wards, has been found to save much time previously spent in marking and sorting, and to obviate the waste of materials which used to occur from the deterioration of unused ward stocks. Rags and waste paper are collected and sold, aluminium is being substituted for earthenware in certain often-broken crockery, such as pie-dishes, and the cleaning of the wards, the supply of tooth-brushes, and the disposal of soiled linen have also been altered. A laboratory has been equipped. The recommendations of the Mental Hospitals Association that increases of pay and bonuses should be given to nurses passing the examinations of the Medico-Psychological Association have been adopted. Nurses are encouraged to make notes on the cases under their charge. The hospital is fortunate in possessing a considerable amount of surplus accommodation.

The annual report of the *Nottingham City Mental Hospital* differs from many other such reports in containing a separate section dealing with mental deficiency. A total of 118 cases has been reported by seven different agencies during the year; there are, therefore, ample facilities for ascertainment. It has been strongly recommended that an institution with at least 300 beds shall be built by the city for the accommodation of its defectives. At present there are 78 cases in various other institutions (including a number of boys at the mental hospital, some of them being warded with men, which is an unsatisfactory arrangement, and some undoubtedly capable of benefit by proper training), 13 cases under guardianship, and 338 under supervision. If the intention of building this institution be carried out, Nottingham will be particularly well equipped for dealing with mental deficiency. Unfortunately, the hospital itself is overcrowded (to the extent of 69 patients), in spite of the boarding out of a number of Nottingham patients in other hospitals, and it is hoped that the provision of the necessary further accommodation may take the form of a detached admission hospital and villas for convalescent cases. It is already intended that a nurses' home and an assistant medical officer's house shall be built. It is observed by the visiting Commissioner that the number of deaths from tuberculosis during the year is almost exactly the same as the number of cases of this disease reported as under observation about a year previously, which "suggests that still further efforts are needed in the direction of diagnosis in the earliest stages." To meet this need he suggests a thorough annual physical examination of every patient, and periodical records of weight, and to combat the disease itself the more liberal use of eggs, milk, and butter in the diet of debilitated patients. The present ascertained cases are being treated on verandahs day and night. Certain suggestions are also made as to employment, the returns under this head being below the average. Money allowances are made to patients on trial. It is also observed that Service patients dine apart from the rest of the inmates.

The annual report of the *Glamorgan County Mental Hospital, Bridgend*, an institution accommodating over 1700 patients, is unusually brief, and includes no visiting Commissioner's report. The only important change in contemplation is the erection of a separate reception block, and a house for convalescent patients; the plans for the latter have already been approved by the Board of Control. A permanent fifth assistant medical officer has been appointed. The engineer has installed an X ray apparatus, and operates it himself with considerable success—surely a very enterprising departure for such an official. Many patients are now allowed to remain up until 10 P.M., and in the summer some are allowed out in the grounds until 9.30, two privileges which are much appreciated and rarely abused. It is of interest that the average gain in weight of recovered cases on discharge is as much as 14 lb.

The report of the *Roxburgh District Board of Control* is concerned with the affairs of one mental hospital, which at present accommodates about 350 patients, 60 less than in recent years, owing to the return of a number of patients to Edinburgh on the reopening of the mental hospital there. No changes are recorded beyond the reconstruction of one of the female wards. It is suggested by a visiting Commissioner that the verandahs should be widened to permit of beds being moved out on to them, and that the female nursing staff, who at present take their meals in the main dining-room before or after the patients, should be provided with a separate mess-room of their own.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDING NOV. 8TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely: Small-pox, 71; scarlet fever, 2106; diphtheria, 1066; enteric fever, 59; pneumonia, 985; puerperal fever, 38; cerebro-spinal fever, 5; acute poliomyelitis, 30; acute polio-encephalitis, 2; encephalitis lethargica, 45; continued fever, 3; dysentery, 2; ophthalmia neonatorum, 106. There were no cases of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 4 deaths from enteric fever, none from small-pox, 14 from scarlet fever, 43 from diphtheria, 26 from measles, 53 from influenza. In London itself the number of deaths from diphtheria was 13 and from infantile diarrhœa 14.

ROYAL SOCIETY.—The following Fellows have been recommended by the President and Council for election to the Council of the Society. President, Sir Charles Sherrington. Treasurer, Sir David Prain. Secretaries, Mr. W. B. Hardy and Mr. J. H. Jeans. Foreign Secretary, Sir Richard Glazebrook. Other members of Council: Sir Frederick Andrewes, Prof. J. H. Ashworth, Dr. F. W. Aston, Sir William Bragg, Prof. S. Chapman, Sir Dugald Clerk, Dr. H. H. Dale, Prof. F. G. Donnan, Prof. A. S. Eddington, Prof. E. S. Goodrich, Sir Thomas Holland, Prof. J. B. Leathes, Prof. T. R. Merton, Dr. G. C. Simpson, Prof. J. F. Thorpe, and Prof. F. E. Weiss. The Earl of Crawford and Balcarres and Sir Otto Beit have been elected Fellows of the Society under the statute which permits of elections on the grounds of conspicuous services rendered to science.

DENTAL BOARD OF THE UNITED KINGDOM.

THE opening of the seventh session of the Dental Board was held on Nov. 11th. The members present were Mr. F. D. Acland (Chairman), Mr. R. C. Ackland, Mr. W. F. Bowen, Mr. L. G. Brock, Mr. F. Butterfield, Mr. W. H. Dolamore, Mr. H. J. Waring, Mr. W. Guy, Sir James Hodsdon, Mr. A. Young, Mr. J. J. Andrew, Prof. T. Sinclair, Mr. J. H. Stirling, and Mr. Norman C. King (Registrar).

THE CHAIRMAN'S ADDRESS.

The Chairman, in his opening address, paid a tribute to the work of those members of the first Board who had not been re-elected: Sir Arthur Chance, Mr. E. L. Sheridan, Mr. W. H. Gilmour, Mr. H. A. Robertshaw, and Mr. D. McG. Cowan. In their place he welcomed Prof. Sinclair, Mr. Andrew, Mr. Ackland, Mr. Bowen, and Mr. Young. Continuing, he said that when the new Dentists Acts were under consideration in the House of Commons he gave an undertaking that the question of the annual practising fee should receive careful consideration. A special meeting of the Board was held in October at which this formed the principal item of business, and the decision of the Board, which was unanimous, was that no alteration in the present fee of £5 should be made until there had been further experience of the claims likely to be made on the Board's funds. It was realised that in these times some members of the profession might well have difficulty in paying a comparatively heavy annual fee, and the question of reduction would not be forgotten.

The Departmental Committee, in view of the monopoly of practice which was to be given to dentists, were of opinion that it would not be unreasonable to expect them to give some assistance to persons who were prevented from entering the profession from want of means, and this the Board had endeavoured to do by providing bursaries, which, in really necessitous cases, provided not only for the necessary fees, books, and instruments, but also for maintenance during the curriculum. These bursaries were brought to the attention of the education authorities throughout the kingdom by means of a circular letter, but the applications had not been so numerous as might have been expected, and so far the Board had not been obliged to refuse any applications owing to want of funds. There was probably, he said, at the present time no other profession in the country into which a student who was qualified to take advantage of professional training might obtain entry practically without any cost to himself, and it might be hoped that the education authorities would continue to bring before their students the advantages offered by the Board.

Free Choice of Dentist.

Many communications, said Mr. Acland, had reached the Board with regard to the action of approved, coöperative, and other societies which, in providing dental aid for their members, did not allow a free choice of dentist. The Board were of opinion that patients should be allowed to select the practitioner whose advice they desired to seek, provided the dentist was prepared to enter into the arrangements made by the society for remuneration. Numerous complaints had, however, been received that the patients of one practitioner had been, through the agency of a society, transferred to another, but it was difficult for the Board to take action except upon a definite complaint that whatever had been done on behalf of a practitioner, or practitioners, amounted to advertising or canvassing. Were such a complaint made, the speaker was sure that the Board would be willing to adjudicate upon it.

The Board considered it highly desirable that the attention of the public should be called to the great importance of the care of the teeth, and with this object they had in preparation kinema films which might be utilised by medical officers of health and others for teaching this subject, and an endeavour was to be made to have them displayed also at the kinematograph theatres. With the assistance of Sir George Newman, it was hoped to arrange for short talks to be broadcasted from time to time, and communications had been entered into with approved societies to endeavour to enlist their coöperation so as to cover the very important period between school age and that of persons coming under the Insurance Acts—viz., the age between 14 and 16. Other methods of teaching oral hygiene were also under consideration, and the Chairman considered this to be one of the most important parts of the Board's work.

Advertising.

The Board had expressed their disapproval of any announcements which were more than sufficient to indicate to persons seeking them the exact location and entrance to the premises at which the dental practice was being carried on. At the present time the correspondence in connexion with this matter was very heavy, and though considerable diminution of the evil was taking place, many practitioners appeared to be keeping up as much of their announcements as they thought they could safely retain, in the hope that, before any drastic action was taken, they would receive a warning, and that in the meantime they would reap such benefit as might be from their improper actions. The Chairman feared that some of them might realise, if their names were removed from the Register, that they had taken a mistaken view of the position.

Practice by Non-registered Persons.

In the course of this year, by permission of the authorities, communications had been addressed to chief constables throughout the kingdom, asking for their coöperation in carrying out the provisions of the Dentists Act, 1921. They had been supplied with copies of the Register, the local lists, and the names of those persons who had not taken out their practising fee. The report of the Discipline Committee showed the very satisfactory result of this action. Without exception the police had been most helpful. In some cases the police had undertaken the prosecutions themselves; in others they had supplied evidence and the Board had taken the necessary action. It was proposed to continue the pressure next year, and the Board hoped that before very long it would be mpossible for any unregistered person to contravene the Acts without being swiftly brought to book.

RESTORATIONS TO THE REGISTER.

The Registrar reported that, the prescribed conditions having been duly fulfilled in each case, the names of the undermentioned persons had been restored to the Dentists Register, from which they had been erased in conformity with the provisions of Section 12 of the Dentists Act, 1878: Arthur Bolton, Arthur Reginald Colyer, Thomas Elliott, Henry Kirk, Edwin Morgan.

DISCIPLINARY CASES.

The Board resumed the consideration of six cases adjourned from the previous session. Two were concerned with registered dentists who had associated hemselves with corporate bodies carrying on the business of dentistry and advertising with a view to procuring patients, and three were cases of advertising, by individual dental practitioners, by means of lectric and other signs exhibited on their premises. n all the cases the Board decided that while they were determined to press forward quite steadily with the work of securing that announcements of dental practices should not be more than would be considered easonable and proper in connexion with other professional practices, they would nevertheless not ecommend the removal of the names of the persons oncerned from the Dentists Register. In one case where the dental practitioner had been convicted at police court for the misdemeanour of indecent xposure, the finding was that the name should not be removed from the Register.

Fourteen new cases were dealt with during the remainder of the first meeting of the session and at the meeting on the following day. Six of the cases were concerned with advertising. In four the finding of the Board was that the names of the dental practitioners involved should not be removed from the Register, and in two the finding was postponed until the next session. There were two cases of false entry in the Register. In the first, the dentist had stated he was engaged in the practice of dentistry as required by the Dentists Act of 1921, whereas he had been in receipt of unemployment benefit. This case was adjourned. In the second, the dentist had made a false declaration of his age; in this case the Board directed the erasure of offender's name from the Register. Two cases of police-court conviction, one for fraud and one for drunkenness, were adjourned. In three cases the names of dental practitioners were removed from the Register, where the offenders had been convicted in the police courts on the following charges, respectively: (1) Ten charges of fraud; (2) living on prostitution and theft; (3) embezzlement and obtaining money on false pretences. For covering an unregistered person in dental practice, the offender's name was removed from the Register. In all, five names were erased.

A NATIONAL SERVICE OF MENTAL NURSES.

SINCE March, 1922, a Departmental Committee of the Board of Control has been deliberating, under the guidance of Dr. C. H. Bond as chairman, on the directions in which the nursing service in county and borough mental hospitals could be improved. Its members include two medical superintendents (Dr. G. F. Barham and Dr. H. Wolseley-Lewis), two representatives of visiting committees (Mrs. Edith How-Martyn and Mr. E. A. Medus), a Commissioner of the Board of Control (Mrs. Hume Pinsent), a matron of a mental hospital (Miss M. M. Thorburn), and members of county and borough councils (Dame Louise Gilbert Samuel and Mr. E. Sanger), with Mr. H. J. Clarke, of the Board of Control, as secretary. Twenty-four meetings have been held, excluding meetings of subcommittees; 12 witnesses have been examined, including a Commissioner of the Board of Control, medical superintendents, members of the General Nursing Council, matrons, and male nurses; moreover, numerous conversations have been held with nurses working at mental hospitals, from whom, as from others, written communications have also been invited.

The report [1] just issued by the Committee is at once temperate, wise, and suggestive. The outline set out early in the report of the principles agreed on by all the members as a foundation on which to build their labours is a useful guide to the point of view from which the subject was approached. The main difficulty which, though not specifically set out, must have modified the conclusions and recommendations arrived at, is that improvement of the nursing service in quantity as well as quality of applicants for training is desired, and that, unless most carefully planned, a recommendation designed to achieve one of these ends may seriously damage the others. For example, the quality of the end-product—the trained mental nurse—may be definitely improved by insisting on a high standard of preliminary education and on the attainment of the certificate of the Medico-Psychological Association; these requirements might have the effect of discouraging probationers of a less ambitious but potentially useful class.

On the whole the recommendations have been well framed to avoid this dilemma, and where any conflict of aims arose, the Committee in every case adopted the high ideal of attempting to improve the quality of the service in the hope that increased status and emoluments of trained mental nurses will make the career attractive to a greater number of educated women.

---

[1] Report of the Departmental Committee appointed to inquire into the Nursing Service in County and Borough Mental Hospitals. London: H.M. Stationery Office. 1924. 1s. 3d.

Grading in Hospitals and Nursing Establishments.

The Committee urge that the nursing service in county and borough mental hospitals should be organised and developed on systematic national and professional lines. To this end mental hospitals should be graded according to adequacy of facilities for training nurses, and individual nursing establishments in accordance with a scheme bringing the nomenclature and status of the higher grades into line with that customary in general hospitals.

Reciprocity Between Hospitals.

Reciprocity for training purposes between mental hospitals of different grades and between each mental hospital and a general hospital is regarded as essential. This organised coöperation is indeed a cardinal feature of the scheme outlined and is a valuable suggestion. It is considered of extreme importance that the facilities already existing in some places for seconding mental nurses to general hospitals should become universal and that authorities should encourage trained mental nurses to take a general nursing certificate, which they can obtain by two years work in an approved general hospital. Conversely, the establishment of training schools in mental nursing would serve as an added inducement for general trained nurses to gain experience of mental disorders and an understanding of elementary psychology, both normal and morbid, which will be found increasingly necessary in general nursing. The Committee feel that the existence of facilities for seconding mental nurses to general hospitals for training is so important that they hope such facilities may be found practicable without any interference with pay or superannuation allowances dependent on continuous service. The scheme of affiliation recommended has for its object the establishment of an organisation of hospitals for training purposes which will secure: (1) efficient and economical use of material and personnel; (2) uniformly sound training and the diffusion of technical knowledge and methods through the widest possible interchange; and (3) coördination between different branches of nursing.

Arrangements for Teaching: Hours of Duty.

As to the improvement of the teaching of nurses, several recommendations are made, including a period of initial tuition for probationers before any ward duty is assigned to them, the appointment of a sister-tutor at each hospital approved as a training school, the provision of annual refresher courses for certificated nurses, and such rotation of duties among sisters as would encourage those aspiring to the higher administrative posts. These, however, should for the most part be offered facilities for supplementing their mental training by two years in a general hospital, for the higher posts should be given only to those with a double training. Those of the present staff with good and satisfactory service, who are unable to obtain the mental nursing certificate, should continue to receive recognition and adequate status; they should be graded as attendants or charge attendants, and there should be a distinction in pay between them and certificated nurses, in favour of the latter. As for remuneration of nurses, it is held that the prevailing rates differentiate inadequately between the inexperienced and the trained personnel, and there is insufficient inducement to study and to advance in the service. The rates paid to similar grades throughout the country are held to vary unduly.

No rigid scheme as to hours on duty has been or, in the view of the Committee, could be laid down, but it is suggested that the aggregate of the hours on duty in one week, exclusive of meal times, should not exceed 56. When the hours exceed 48, four weeks' annual leave, preferably taken as two weeks every six months, should be allowed to all certificated nurses. Probationers under training should be allowed three weeks' annual leave.

Special nurses, to whom could be allotted the charge of any individual patient at the discretion of the medical staff, should be available.

The Financial Aspect.

Certain other recommendations are concerned with the means of attracting suitable applicants for training. It is believed that, with the institution of organised universal training and the creation of adequate prospects, the status of mental nursing will be considerably raised, and there will be less difficulty in the recruitment of suitable personnel. Inasmuch as training must entail some expense, the Committee are of opinion that probationers should be bound by agreement to remain for the full period of training.

This recommendation seems to us likely to defeat its object. Stress is laid on the fact that the nursing of mental patients should be looked on as a vocation and not undertaken lightly. The work is, however, difficult to visualise beforehand, and the dread of being pledged to remain in a mental hospital for three years' training for work which after trial may prove uncongenial is likely to prevent educated girls or their parents from considering this career. The actual cost of training would be equally wasted if the candidate were to stop nursing after having acquired her certificate and the only thing gained to the hospita might be three years of unwilling service. The Committee's further suggestion for meeting the cost of training of nurses is a sound one. Inasmuch as training schools will not and cannot be self-supporting institutions, and in view of the fact that it is of national importance to secure properly trained nurses for mental hospitals, the Committee is of opinion that a portion of the cost of maintaining recognised training schools should be met out of a Government grant administered by the Board of Control.

Increased Powers for the Board of Control.

A strong appeal is made to visiting committees to give effect to these recommendations, and it is made clear that success of any such scheme depends on its adoption throughout the country. The appointmen upon the inspectorate of the Board of Control of a doubly-trained nurse of wide experience and capacity who would maintain close touch with questions of nursing in mental hospitals throughout the country and be at the service of the various medical and nursing officials as an adviser, is suggested. At present too little coördination exists between the various local authorities controlling the mental hospitals throughout the country for them to develop a mental nursing service on a national basis. The suggestion which concludes this admirable report deals with this aspect as part of an even wider one. The Committee see a solution for this and other problems in enlarging the scope and extending the power of the Board of Control from that of an advisory body to that of a body responsible for administering a Governmen grant-in-aid. They say: "While the subject is not strictly within our reference, our inquiry has impressed us with the need for concentrating the responsibilities in connexion with mental health in one statutory committee of the county or county borough council. We are further of opinion that the cost of the maintenance of mental cases, at present defrayed by Poor-law authorities, should be a charge upon the county or county borough rate; and that a proportion of the cost should be borne by a Government grant distributed by the Board of Control with power for the latter to withhold it in cases of inefficiency."

It is likely that in this direction will be found the solution not only of the nursing, but of many other cognate problems.

Correspondence.

"Audi alteram partem."

THE ALLEGED STERILITY OF PRESENT-DAY BACTERIOLOGY.

To the Editor of THE LANCET.

SIR,—In a leading article in your issue of Sept. 20th your readers are informed that bacteriology is in a stagnant condition and that no discovery "of first-rate importance" has been made "for many years." Sentiments in surprisingly similar vein are expressed by Prof. A. E. Boycott in the course of his address at Montreal, reported in your issue of Nov. 15th. The undiscriminating reader must inevitably conclude that bacteriology is in a parlous state, but is there really the smallest justification for these gloomy views? When a writer uses the expression "for many years" we may assume that he means at least 20. Are there no discoveries "of first-rate importance" to catalogue to the credit of bacteriological science in that period? Perhaps I should avoid the word *science* at this juncture. Let me say "utilitarian bacteriology."

Since 1904 it has revealed the specific causes of syphilis, yaws, epidemic jaundice, and yellow fever, to mention only a few instances culled from human disease. It has gone far to elucidate the specific ætiology of poliomyelitis, typhus fever, trench fever, and quite recently of scarlet fever, while it has made possible the solution of many pressing epidemiological problems, such as the spread of typhoid and allied infections, of Malta fever, and of bubonic plague. Of the results of coöperation, in an equally utilitarian manner with its sister science, immunology, may I mention the Wassermann test, the Sachs-Georgi test, the Wilson-Weil-Felix test, the Schick test in diphtheria, and the Dick test in scarlatina? I need instance no more, as Prof. Boycott would doubtless class them as thoroughly third-rate, because utilitarian. To him they are finished, and consequently devoid of uplift and inspiration to the philosophic mind. By the same token, I presume, insulin would cease to inspire the physiologist and biochemist the moment it was found to possess some value in the treatment of diabetes. Let those who will or who cannot help it go on exploiting these discoveries in the cause of pathological diagnosis and public health. Scientific bacteriology must take no concern with them. It must develop and foster the study of bacteria for their own sake, whatever that may mean. It must find out how micro-organisms generally live, move, and have their being away from such contaminating influences as association with other living things, be they plants or animals. This, to Prof. Boycott, but I hope to few besides, is envisaged as a virgin field and should be handed over to the botanists who would then become the exponents of scientific bacteriology.

Well, if bacteriology was started on its way by a chemist of immortal fame and strictly utilitarian outlook, it, most fortunately for humanity, did not find a home in the botanical nursery. If scientific bacteriology is now to be nursed by the botanists I have no objection, but I am quite satisfied that the lack of the medical tradition, with its highly elaborated technical methods, will handicap them for many a day in their dealings with bacteria. Let me instance what is in my mind. In the field of systematic classification can the botanists afford to cling to old-fashioned morphological criteria and ignore the biochemical and serological elaborations of the "old hand"? Surely not. And have the old hands done really nothing in this academic field? To be sure they have. Unlike Prof. Boycott, enterprising spirits have found even the Wassermann reaction an inspiration, and have rightly studied its raison d'être as a pathological problem, not as a pathological curiosity as Prof. Boycott seems to regard it. Does it stand so unrelated? Have we not the Weil-Felix and possibly many other non-specific precipitation phenomena? Have we not also our exponents of bacterial cycles, nay even of theories of hybridisation in bacteria? That the work of these latter has so far cut but little ice is probably due to a combination of circumstances, among which exuberant imagination and inadequate technical training are pre-eminent.

I protest strongly against any insinuation that bacteriology has ever threatened to stagnate since those halcyon days of the 'eighties, when a man might immortalise himself any morning by finding a diphtheria bacillus or a trypanosome. We bacteriologists are the proud possessors of a superstructure of traditional knowledge and achievement that will inspire us to further endeavour for many years yet, but I should err if I were to assume that all is well and well-ordered in bacteriology. Our science has grown beyond all conception in recent years. No one man can keep abreast with its advances in animal and plant pathology, not to speak of its ramifications in diverse industrial fields. A survey of the labels on the culture tubes of the National Collection can but impress the expert in a branch with a profound sense of ignorance and humility.

Can anyone, then, dictate what particular feature of bacterial life and action is best worth study from the standpoint of academic culture? The recently instituted courses at Manchester and elsewhere will doubtless foster a broader outlook in bacteriology, but they cannot afford to lose the inspiration that our traditional and utilitarian bacteriology can give them. All success to them!

I am, Sir, yours faithfully,
J. C. G. LEDINGHAM.

Lister Institute, London, Nov. 17th, 1924.

DENTAL DRESSERS.

To the Editor of THE LANCET.

SIR,—The Secretary of the British Dental Association calls the Dentists Act of 1921 "a sacrifice" on the part of the dental profession. The Act has placed the dental profession in a position held by no other body of men, medical, legal, or industrial. Under the Act no one unless on the Dental Register may practise dentistry in any way. If a child has a loose shell of a temporary tooth and the mother, teacher, or nurse removes it with a piece of cotton, it "would render the operator liable to prosecution." If we doctors had a similar Act, the Jews could not perform circumcisions, the chiropodist could not cut corns, the profession of midwife would be abolished, and the Church and the Christian Scientists could not do their healing by faith.

The Act has placed the dentists in a privileged position, but there was one little section inserted for the protection of the public enabling "minor" work to be done in a public dental service under the personal supervision of a registered dentist, on conditions laid down by the Minister of Health. For years educated young women, specially trained in the detection and treatment of early caries, have been employed in Derbyshire, Shropshire, Sheffield, &c., under the supervision of the school dentists. Mr. Lindsay ignores the fact that these dental dressers are *trained* and passed by dentists. In my report (a copy of which I will gladly send to any of your readers) I give details of their training. If it is insufficient, by all means let us make it more thorough. The Minister of Health has power to prescribe the training. Let there be, too, an examination in the work they will have to perform. This is done in New Zealand; why not here? The work of our dental dressers has been examined by six eminent dentists, and no one has been able to detect any fault with it.

Now let us look at Mr. Lindsay's proposals. He writes: "The school nurse can by a glance into the mouth of a child and by one or two simple questions ascertain whether there is need for the child to go to the school dentist." This means that caries is to spread in the teeth of the school-children until a nurse can see a hole or the child has pain. This is all wrong.

By employing specially trained young women, expert with probe and mirror, we detect and refer to the dentists incipient caries at its earliest stage, when prophylactic permanent fillings can be inserted without pain. This is the bulk of the work; all doubtful cases the dentists deal with themselves. If dental dressers were permanently recognised we could employ more part-time dentists in private practice. If a dentist devotes his whole time to school work without the assistance of dental dressers, in a few years he will forget all the higher branches of his profession. The best men, recognising this, will resign, and only the indifferent practitioners will remain in the school dental service. Putting the whole of the work, including the inspections in the schools, on to dentists without the assistance of dental dressers would lead to an inferior type of practitioner, and the salaries paid would be small. But if a dentist had dental dressers working under him he would command a higher salary, and his work would be more interesting.

Mr. Lindsay's comparison of trained dental dressers with unqualified medical assistants is wide of the mark. The trained midwife reigns in the stead of the unqualified assistant, and in this county carries out 70 per cent. of the midwifery. If the British Dental Association had investigated what we are doing, I am sure Mr. Lindsay would never have written his letter. If they would do so now and they found our work is not of the highest professional standard, I will withdraw my advocacy of dental dressers. In my letter of Oct. 6th I pointed out the necessity for dental benefit being provided under the Insurance Act, that nothing is yet done for children under school age and for expectant mothers, and next to nothing for the tuberculous patients. All this work cannot be done unless trained dental dressers are employed working under the supervision of dentists.

Mr. Lindsay and I ought not to be engaged in wordy warfare, but should be putting our heads together to approach such agreement as might be of help to the Ministry in preparing a Public Dental Service in which those dentists in private practice who have the time may take part.—I am, Sir, yours faithfully,

Derby, Nov. 17th, 1924. Sidney Barwise.

To the Editor of The Lancet.

Sir,—The discussion of the dental dresser seems now to have reached essentials. It is the "dental hygienist" whom I would like to see acclimatised and given responsibility. This officer appears to be approved by Mr. Breese, and Mr. Lindsay says is sanctioned by Circular 1279. It is this circular which raises the administrative trouble, because it insists on the work being done under the eye of the dentist, thereby restricting the numbers and making it more costly. That is where the hold-up comes in the school dental work; and that is why the numbers of dentists on the Register were not germane.

The next question as to whether anyone can be trusted to do simple fillings, extract deciduous teeth, or 6-year-old molars one would think should answer itself. I believe that anyone, not a moron, could easily attain a satisfactory proficiency here with a special 12 months' training. It is certain that the majority of deciduous teeth will continue to be extracted in the absence of either a dentist or dental dresser. Although a caveat might be entered on behalf of the 6-year-old molar I would be disposed to go as far as Dr. Barwise, and trust it also to the dental dresser to handle or refer for further dental advice. It was the tooth whose fate first concerned me in school inspections 30 years ago. The consensus of various dental advisers then was that for board school children it was not worth troubling to do anything here but extraction, a counsel which never, however, commended itself. Within the past 12 months advice was given in a prominent discussion to remove adolescent 6-year-old molars for prophylactic reasons.[1] Evidently the confiding of these teeth also to the dental dresser does not involve disaster. Possible dangers must be absolutely negligible compared with the risks of midwifery where officials of a corresponding status act for the public advantage.

School hygiene in England has been in a condition of stasis for years now, with the exception of the beginnings and advance of this matter of dental hygiene whose promise is already great, so great that as soon as it becomes known the country will demand full care. So pressing is the need that it would be worth while establishing dental hygienists in responsible work under definite rules and control, and leaving the discussion of extractions over till prophylaxis by instruction and example has got well into action, the numbers requiring dental operative work will then begin to fall and the question may never arise. The immediate call is for removal of the hampering regulation of only working under the personal supervision of the dentist, and restricting the number who may so work. This circular practically puts the work as a matter of educational organisation out of court, reducing its volume to a fraction, apart from the unnecessary increase of cost.

I am, Sir, yours faithfully,

Mecklenburg-square, W.C., Nov. 17th. James Kerr.

CANCER AND SOME OF ITS SIGNIFICANT CHEMICAL REACTIONS.

To the Editor of The Lancet.

Sir,—I was most interested to read in your columns of Nov. 1st Mr. Archibald N. Currie's reply to my letter on the above subject, especially as we are more or less in agreement on the various points raised. There is, however, some little misunderstanding due probably to the rather vague way in which I expressed my experimental findings.

The importance of the rôle of cholesterol in the iodine values of fat in carcinoma cases was queried by Currie. I did not mean to imply that the increased unsaturation was directly proportional to the increased cholesterol content and a single example will clear this point. Using pure cholesterol from the human brain and pure triolein, an extreme mixture of 72·7 per cent. cholesterol with 27·3 per cent. triolein (i.e., 0·12 g. cholesterol and 0·045 g. triolein) had an iodine value of 65·5, a value which is considerably less than that of either cholesterol or triolein. This is, perhaps, not unexpected and is reminiscent of the phenomena seen in mixed melting points of substances. Nevertheless, the iodine value is greater than that given as "normal" for adipose tissue. Thus it appears that the amount of cholesterol present has a distinct bearing on the iodine value. Also from the intensity of colour in the Borchard-Liebermann test it is obvious that the cholesterol is not present wholly in the free state but a little is in the ester form—viz., as palmitate and oleate. An increase or decrease in the blood cholesterol is so influenced by a multiplicity of conditions, diet being the chief, that estimation of the cholesterol content cannot possess any diagnostic value. However, in the Shaw-Mackenzie serum test for cancer, cholesterol apparently does have a function.

With regard to the lipoclastic activity which was another point raised by Currie, it is generally recognised that the free fatty acids, whether saturated or unsaturated, are more utilisable by the tissues than are the fats themselves. Freund and Kaminer in 1913 found that there was a decrease in the fatty acid content of cancer serum as compared with the normal, and more recently Waro Nakaharo (*Journal of Experimental Medicine*, 1924, Vol. XL., p. 363) finds that oleic, linolic, and linolenic acids have a distinct immunising action against transplanted cancer in mice. Therefore, it seems possible that deficient lipoclasis may play a part in cancer.

I am, Sir, yours faithfully,

H. Gordon Reeves, M.Sc., A.I.C.

Department of Physiology, King's College,

LABORATORY CHANGES AT A HOSPITAL.

To the Editor of The Lancet.

Sir,—Our attention has been drawn to a circular sent to the medical practitioners resident in the N.W. district of London by the Secretary of the Hospital for Epilepsy and Paralysis, Maida Vale. This circular states that the committee of the hospital had now arranged its laboratory "with a biochemist and bacteriologist," and would be willing to undertake clinico-pathological examinations for the doctors in its neighbourhood. A list of fees for individual examinations was enclosed.

The secretary of the Maida Vale Hospital seems to have hit on an arrangement whereby the laboratory may appear on the "asset" side of the hospital balance-sheet; we think it is only fair to point out to the practitioners concerned that the arrangement has only been made possible in this instance by the elimination of the ordinary type of hospital pathologist. The laboratory staff of the Maida Vale Hospital consists at present of (1) an honorary pathologist, who is one of the junior honorary medical staff and who is also neurologist to a large teaching hospital, and whose time is therefore largely occupied with teaching and clinical work; (2) a graduate in science with some training in an asylum laboratory; and (3) other technical assistants. The description of the staff as including "a biochemist and bacteriologist" is therefore somewhat misleading.

We are, Sir, yours faithfully,
J. G. Greenfield.

COMPLETE TRANSPOSITION OF VISCERA.

To the Editor of The Lancet.

Sir,—Cases of complete transposition of viscera are not so very common, hence it seems desirable to record this. A Hindu boy, aged 8 years, attended the out-patient department of the Medical College Hospital for treatment of kala-azar. Palpation of the abdomen revealed a tumour in the right hypochondriac region, extending downwards and inwards to about the level of the umbilicus. This tumour had a splenic outline and there was a distinct notch in its anterior margin. The liver was felt in the left hypochondrium and was slightly enlarged. The boy was admitted into hospital on August 16th, 1924. X ray examination showed the heart on the right side of the chest. Skiagrams of the abdomen taken after a bismuth meal showed that the stomach was mainly situated on the right side of the abdomen with its cardiac end under the right cupola of the diaphragm, and the duodenal bulb on the left side of the middle line. The cæcum and the ascending colon were found on the left side. The descending and sigmoid colon was situated on the right side of the abdomen.

I am, Sir, yours faithfully,
N. C. Kapur, M.R.C.S. Eng.,
Capt., I.M.S.
Calcutta Medical College Hospital, Sept. 30th, 1924.

QUININE IN CASES OF ERYSIPELAS.

To the Editor of The Lancet.

Sir,—The use of Warburg's tincture in tropical countries for a large variety of ailments suggested to me the extended use of quinine in this country, and during the past 23 years I have substituted quinine for salicylate of soda and never regretted having done so. In cases of erysipelas quinine acts like a charm, the patients feeling so well generally that their sole desire is to resume their duties irrespective of appearances. The local lesion is treated by quickly brushing over the affected area (and 1 inch beyond, if possible) an application made up of one part of tincture of iodine to seven parts of Keith's anæsthetic ether, once daily. The general treatment consists in giving orally, every two hours, 10 gr. of sulphate of quinine undissolved, 10 minims of spirit of chloroform, and ½ minim of essence of peppermint in 4 oz. of cold milk. When the temperature and pulse become normal, or nearly so, reduce to every six hours. Erysipelas is fortunately a rare disease nowadays and it is impossible to give statistics as one can do in other diseases. Nevertheless, the results obtained during the past 11 years seem to justify anyone trying the above treatment, and I am convinced that they will not be disappointed.

I am, Sir, yours faithfully,
John Wishart, M.D., D.Sc., F.L.S.
Newcastle-upon-Tyne, Nov. 14th, 1924.

THE VENUE OF THE REX *v.* HADWEN TRIAL.

To the Editor of The Lancet.

Sir,—In suggesting that "partisan" feeling decided the finding of the jury in the above case, your legal correspondent puts himself in a two-fold dilemma.

1. If a Gloucester jury could not be trusted to give a verdict against Dr. Hadwen by reason of partisanship, how were nine men out of twelve found to give such a verdict at the coroner's jury?

2. If a Gloucester jury was bound to favour Dr. Hadwen, why did the coroner send an affidavit to the King's Bench Division urging the change of venue "in the interests of the accused, as well as in the interests of justice"?

May I challenge a reply to these questions?

I am, Sir, yours faithfully,
Beatrice E. Kidd,
Secretary, British Union for Abolition of Vivisection.
32, Charing Cross, S.W. 1, Nov. 8th, 1924.

⁂ The correspondent whose remarks Miss Kidd criticises writes as follows: "The Secretary of the Anti-Vivisection Society has sharpened the four horns of her admirable dilemma in vain, for nobody but themselves can say what was in the mind of (1) the jurymen, or (2) the coroner. It is only fair, by the way, to the latter to recall that the Lord Chief Justice in dismissing the application to change the venue observed that the prosecution had 'looked at the matter with the utmost impartiality.' Are we not agreed on the general principle that trials are best conducted in a calm atmosphere, just as cricket matches are best played without barracking? Whether the atmosphere of this trial was ideally calm is perhaps a matter of opinion on which I may have been mistaken, but the judge's rebuke to the spectators after the verdict confirms the impression I had received from the newspaper reports."—Ed. L.

A DISCLAIMER.

To the Editor of The Lancet.

Sir,—My attention was recently called to a pamphlet entitled "The Ætiology and Treatment of Pyorrhœa," published by the Ainslie-Walker laboratories, in which a quotation has been made from a note of mine in The Lancet without my knowledge or consent. A letter to the firm produced the amazing statement that "the quotation in such cases is of itself a compliment, to which I learn with surprise you seem to take exception." Under the circumstances I shall be obliged if you will give me the opportunity of stating not only that I do not agree with the treatment of the cases to which I referred in the note by intestinal "disinfection" with dimol, but that I am opposed to this procedure.

I am, Sir, yours faithfully,
A. Knyvett Gordon, M.B.
10, Bedford-square, W.C. 1, Nov. 18th, 1924.

Obituary.

JOHN FRANCIS WALKINGAME TATHAM, M.A., M.D. T.C. DUB., F.R.C.P. LOND. & IREL.

SINCE his retirement from the post of Superintendent of Statistics at the General Register Office in 1910, Dr. Tatham, whose death took place at his residence in Oxted, Surrey, on Nov. 8th. at the age of 80, had lived a retired life, first at Lynton in Devonshire and afterwards at Oxted, and his old friends and colleagues had but few opportunities of meeting him. A few years ago he took Holy Orders, thus following his son who died before him, and he did useful and unassuming work in the Church.

John Francis Walkingame Tatham received his medical education at the University of Dublin, taking also qualifications at Glasgow. He went quite early into the public health service, and his first appointment, which gave proof of mastery of the principles of vital statistics and their application to preventive medicine, was that of medical officer of health for Salford, now some 50 years ago. He had there to struggle with the numerous insanitary conditions and the bad housing of a densely populated area; but already his statistical leaning was evidenced in the elegant and valuable statistical tables published in his annual reports. To these tables he evidently devoted great study, and they contained in manageable form most valuable comparisons between the current experience of Salford and that of other urban communities.

With his appointment as medical officer of health of the twin city of Manchester, Dr. Tatham's responsibilities and opportunities increased. From the point of view of efficiency of public health administration his post could not be described as a happy one. There was an unnatural divorce between the medical and sanitary work of the city, while he had no control over or claim on the time of the inspectors of nuisances employed by the corporation. To some extent this difficulty was met by utilising the district health nurses of the Manchester and Salford Sanitary Association; but these were relatively unskilled persons, and there can be no doubt that for some years epidemiological inquiries were carried out in Manchester in circumstances which hampered efficiency. The recognition of the work of these women had important indirect effects, for they can be regarded as the forerunners of the health visitors who are now in the van of child hygiene in this country.

Dr. Tatham's reports on the health of Manchester were characterised by the same statistical care as his earlier reports for Salford. In the year 1892 he published the first "Manchester Life-table," in which we see the earliest outcome of his friendship with Mr. Noel A. Humphreys, of the General Register Office. Mr. Humphreys made valuable suggestions as to the life-table, and Mr. A. C. Waters of the same office undertook the mathematical section; but the text of the report is Dr. Tatham's own, and displays a mastery of the problems concerned. Perhaps the most interesting part of the report is his answer to the question set at an earlier date by Mr. Noel Humphreys, "Are we young longer, or mature longer, or old longer?" Without going into detail, the conclusion reached is that men aged 25 in Manchester lose 1/6 of their normal period of maturity (ages 25–65), and 1/10 of their normal period of decline. One of the chief uses of a life-table is to enable a summarised statement to be given of the relative vitality in different communities; thus Dr. Tatham's life-table made it possible to state that in 1881–90 the future life-time of males in Manchester township was 28·8 years, as compared with 34·7 years in the whole city, and with 40·7 years in London and 43·6 years in Brighton. Subsequently Dr. Tatham published a second Manchester life-table, dealing with the experience of 1891–1900, and this was almost simultaneous with his transfer to the post of Superintendent of Statistics at the General Register Office, on the resignation of Dr. W. Ogle.

Dr. Tatham thus succeeded to the office which William Farr had made an essential part not only of the science of statistics, but also of the history of public health progress; and his friendship with Mr. Noel Humphreys, who had for many years been closely associated with Farr, ensured continuity of policy and work. But prior to this Dr. Tatham had initiated work in connexion with the registration of disease with which his name will perhaps be longest remembered. Following on earlier attempts by the Metropolitan Association of Health Officers in 1857, Dr. Arthur Ransome and the Sanitary Association of Manchester and Salford in 1860 organised a system of registration of sickness for these towns which appears to have been fairly complete, and which was not finally abandoned until the appearance 25 years afterwards of the compulsory notification of infectious diseases. Later it became realised that although preventive medicine is not confined to action against communicable diseases, prompt information respecting these is the urgent desideratum; and so town after town, from 1877 onwards, obtained local powers from Parliament making compulsory the notification of each case of the chief infectious diseases to the local medical officer of health. Then, and not until then, could it be said that the health officer was, in respect of many diseases, doing more than following slow-footed in the wake of disease. But disease does not confine itself to municipal or other local boundaries. The development of the complete possibilities of these returns of infectious diseases necessitated collateral information as to the amount and nature of the infectious diseases prevalent in neighbouring districts and in the rest of the country, or even in other countries. Dr. Tatham early recognised this defect and at the beginning of 1888, while still medical officer of health of Salford, he made a private arrangement with the medical officers of health of 32 other notification towns, by which he should receive from them weekly returns of the cases notified in each town. These were tabulated by him, and then circulated confidentially among the contributing medical officers early in the succeeding week. This was one of the many occasions in which private enterprise has experimented in pioneer work until official inertia can be overcome and the work can then be done on a national scale. The practicability and the utility of this voluntary inter-notification having been fully established, many of the local authorities concerned petitioned the Local Government Board to take the matter in hand as a "going concern"; and in 1889 the Board undertook this task. It may be added that this official work was made complete for the whole country by an Order of the Local Government Board in 1910, which made it the duty of every medical officer of health to forward the necessary returns weekly, which are printed for all areas and circulated later in the week. There have been more recent developments of the same policy which cannot be stated here, but to Dr. Tatham belongs the credit of initiating a most important development of intelligence work.

The best of Dr. Tatham's work in the General Register Office is embodied in the two letters to the Registrar-General summarising the vital experience of the country during the two decades 1881–90 and 1891–1900. They are indispensable to the English student of vital statistics; and a modestly expressed hope in the first of these that "these volumes may be regarded as a not unworthy contribution to the series of supplementary reports of which the first and second were written by Dr. Farr himself and the third was from the pen of my eminent predecessor. Dr. William Ogle," was realised in the event. Part I. of the first of these reports dealt with mortality in general and gave the life-table experience, while Part II. dealt chiefly with occupational mortality. In the corresponding supplement for 1891–1900 Dr. Tatham had the advantage of dealing with corrected or standardised death-rates in which there had been eliminated the disturbing influence of accidental variations in the proportion of the two sexes and of persons at different ages. In his life-tables he was able to show the steady improvement in vitality during the course of civil registration in this country, and to display the age-incidence of this improvement.

Tatham was cautious in judgment, and stated his conclusions with clearness and brevity. In personal relationships he was courteous and helpful, and many medical officers of health have cause to remember his guidance and help with gratitude. The record of his work remains, and deserves to stand as a proof of the value of vital statistics in their intimate affinity with the progress of preventive and curative medicine.

In addition to the official literary work mentioned, Tatham was the author of the article on medical statistics in Allbutt and Rolleston's "System," while he was also a frequent contributor to these columns on the same subject. He was the chairman of the Statistical Committee of the Imperial Cancer Research Fund, a member of the Privy Council Committee on Physical Deterioration, a past President of the Epidemiological Society, and had held examinerships in the Universities of Cambridge and Wales.

JOHN BENJAMIN HELLIER, M.D. LOND.,

CONSULTING OBSTETRIC PHYSICIAN, LEEDS GENERAL INFIRMARY.

Dr. J. B. Hellier, Emeritus Professor of Obstetrics in the University of Leeds, died at the age of 71 at his home in Leeds on Nov. 8th after a short illness. Dr. Hellier was a student of Leeds, and spent his whole professional life in that city. He qualified M.R.C.S. Eng. in 1875, and soon after his graduation the following year at London University, where he took first-class honours in medicine and was awarded the gold medal in obstetrics, he became associated with the Leeds school as one of its teachers, acting for some time as demonstrator of anatomy. In 1878 he obtained the M.D. Lond. He was then appointed lecturer on materia medica, and though by this time he had made up his mind to devote himself to obstetrics and gynæcology, he was active in the duties of the post and founded the museum in connexion with that subject. He was for a good many years in general practice, and it was not until he became associated with the Women and Children's Hospital that it became clear to all that he was destined to fill an important place as a consultant in this department of medicine and surgery. From being lecturer in gynæcology he was promoted to the chair of obstetrics, which he held till the year 1918. In 1899, on the resignation of Dr. James Braithwaite, he was appointed to the department of obstetrics and gynæcology at the General Infirmary. For many years, therefore, Dr. Hellier had great opportunities of serving his old school, and the school has never had a more loyal and trustworthy officer. He was an impressive and interesting lecturer, and devoted much care to the preparation of his lectures, feeling as he did that the value of lectures was frequently underestimated from a lack of proper attention to this. In harmony with the rules of the two institutions he resigned the chair of obstetrics in 1919 and the honorary post of gynæcologist at the infirmary in 1918. The University at once showed its appreciation of his services by conferring on him the title of Emeritus Professor. Automatically he became consulting gynæcologist at the infirmary, with the right to use six beds. Thus, as is and has been for many years at Leeds the happy custom, he was able to carry on his extensive consulting practice without losing touch with the infirmary. Some few years ago his health began to fail, and he made a voluntary and gradual retirement. He was an outstanding figure in the medical life of Leeds, and his long association with the school, both as teacher and valued adviser on questions of policy, was an important factor in its successful development.

Prof. E. O. Croft sends the following appreciation: "As a colleague of the late Dr. J. B. Hellier of some 35 years' standing, it is fitting that I should express, however inadequately, some note of appreciation of the character of one whom we, at the University of Leeds, shall all miss very sincerely. When Chas. J. Wright was professor of obstetrics, I was demonstrator of midwifery, and Hellier shortly after, in 1889, became lecturer in gynæcology and gynæcologist to the Hospital for Women, where he and I worked together for some years until he joined the infirmary staff. At the medical school, the University, and hospitals we were continuously associated and did our last day's work together as recently as last month as co-examiners for the Central Midwives Board. On that occasion it was obviously only his indomitable courage that carried him through, and we realised he could do no more. He and I on various occasions were associated in carrying out necessary changes and developments in hospital and teaching affairs, and I think no one can realise more than I the high-minded and unselfish attitude he took in all such matters. Whatever differences of opinion might have existed Hellier was always the courteous gentleman, who never allowed any personalities to arise, and whether his views and suggestions availed or otherwise he remained the same kindly friend—a true sportsman—ready to try again. Hellier had a somewhat abrupt manner in conversation, but it was never tinged with any trace of unkindliness. He was a man of considerable culture and devoted to literature. One of his greatest and most valuable assets was a very keen and deep sense of humour: we can all remember many fascinating and interesting addresses and speeches with which he entertained us at University and medical gatherings. Hellier as a hospital colleague, teacher, and friend, and even more as a man of high character, exercised a great influence for good among all who knew him."

Dr. Hellier was a Fellow of the Glasgow Obstetrical Society, and was twice elected as President of the North of England Obstetric and Gynæcological Society. He made some sound contributions to medical literature in his own subject. In 1908 the second edition of his useful introductory manual on "Infancy and Infant Rearing" was published. This book was designed for a wide audience of pupil midwives, health lecturers, students, and practitioners, and well fulfilled its object. He contributed the article on Fistulæ in the Female Genital Tracts to Eden and Lockyer's "System of Gynæcology," and to Latham and English's "System of Treatment," the chapter on Diseases of the Vulva. In addition, his papers were frequently published in THE LANCET and various medical journals.

He has left a widow, daughter of Mr. H. B. Harrison of Manchester, two sons and two daughters, one of whom is in the medical profession. To them we extend our sympathies.

GEORGE ERNEST HASLIP, M.D. BRUX., M.R.C.S. ENG., D.P.H.

Dr. Haslip's death on Nov. 12th was for him a happy release from long and painful illness, but a severe loss to a wide circle of medical interests Born in 1864, he studied at the London Hospital, taking his conjoint qualification in 1887, and supplementing it with the Brussels M.D. two years later. After filling a series of house appointments at his hospital, he began his practice in London, where he was brought closely in contact with business men, and became himself a competent man of affairs. He was elected a member of the Consultative Committee of the Ministry of Health, and took an active part in all medico-political matters in the metropolitan counties. His connexion with the British Medical Association included all the active years of his life; he devoted time, energy, and native wit to its welfare, ultimately becoming treasurer. Of this phase of his life Mr. N. Bishop Harman writes:—

"Of George Ernest Haslip it may be said that there were few men who made so many friends and so few enemies. It is even doubtful if he made any enemies at all, but of friends that they were many is certain. Yet there are few men who have played a wider part in the medical affairs of his time. For eight years he filled one of the highest offices in the British Medical Association, the treasurership, and his tenure of office covered most of the difficult period of the war and the years of reconstruction. In the discharge of the duties of his office he showed an easy vigilance which was invaluable in the administration of the affairs of the Association, especially when there came one of those inevitable changes within the permanent staff of the head office, which might under less skilful guidance have made the wheels run heavily, but his care forestalled such risks. In finance he showed both knowledge and judgment. His work as treasurer did not diminish his attention to local medical matters, and it is common knowledge that his work in the Metropolitan Counties Branch and in his own division was unflagging.

"Haslip held strong views on professional affairs. Sometimes others of us considered them somewhat different from our 'doxy. He never hesitated to express his views, sometimes with a vigour that might have been wounding. Yet he never wounded. He had a way with him—so kindly, so single-minded, and so impersonal, that the keenest dissension in debate left no soreness, so that it came to pass on many such occasions apparently sharp antagonists would be seen strolling home with him in some happy discussion or converse that smoothed out any ripple of stress. As a medical practitioner he was unremitting in the care of his patients. To meet him in consultation was to discover that of all his many activities the care of his patients came first. To this end he spared no pains to keep himself abreast of the best practice he could find.

"The fibre of a man's character is revealed in his reaction to conditions of grave strain. Haslip's long and exhausting illness, with the constant suffering it entailed, was borne with a fortitude that was exemplary and not to be forgotten. Those who saw him then, when the signs of physical weakness were manifest, were the better for the lesson of his uncomplaining endurance. As one who had the honour to be his colleague in many a venture in Association affairs, I can give thanks for his work and for his example."

Dr. Haslip took an early interest in the Medical Insurance Agency, and was for the last year or two of his life chairman of the committee of management. The first part of the funeral service was held at St. Martin's-in-the-Fields on Nov. 14th; the second part at Walton-on-the-Hill, where he had long had a country house.

CHARLES FREDERICK ARROWSMITH MOSS, M.D., C.M. EDIN.

Dr. C. F. A. Moss, who died recently in Madagascar at the age of 59, devoted his life to medical mission work in that island, under the London Missionary Society and the Friends' Foreign Mission Association. He was the son of the Rev. C. F. Moss, also a missionary of the former society. Dr. Moss was born at Gosport in 1865. After studying medicine in Edinburgh University, where he graduated as M.B., C.M. in 1888, he went to Madagascar in the following year, and obtained his first appointment with the Friends' Foreign Mission Association, at the United Hospital at Tananarivo. He was in the hospital when it was bombarded and taken by the French in 1895. He married, in 1897, Rose Mary Pearse, daughter of the Rev. Joseph Pearse, the pioneer missionary of the L.M.S. to Madagascar, whose life he wrote 11 years ago. In 1898 he gained the M.D. Edin. with commendation. In 1913 Dr. Moss was placed on the retired list of the Friends' Foreign Mission Association, but he continued as a medical missionary at Tananarivo until 1920, when he was appointed by the London Missionary Society to a medical post in Imerimandroso in the Antsihanka Province, where he died. He visited England in the early part of last year, and was expecting to return home for good in two years' time. His widow is at present in this country.

JOHN LAWRENCE RENTOUL, M.B., CH.B. EDIN.

MUCH regret is felt in Belfast and the North of Ireland at the recent death, in early middle age, of Dr. J. L. Rentoul. A son of the late Rev. James Rentoul, of Dromore, Co. Down, Dr. Rentoul graduated as M.B. Edin. in 1900 and began practice in Lisburn, where he established a large clientèle. He volunteered for war service and obtained a commission in the R.A.M.C. He had given much attention to bacteriology, and was appointed bacteriologist to the hospital ship *Britannic*, which was torpedoed in the Ægean Sea in 1916. Dr. Rentoul was rescued, and subsequently had charge of a field laboratory in France. After demobilisation he settled in Belfast and practised as a clinical bacteriologist. He was an active member of the Ulster Medical Society and contributed frequently to its proceedings. He was specially interested in tuberculosis, and was engaged in experiments with a new serum at the time of his last illness. He was very popular with his friends and colleagues, and to his widow we extend our sympathies.

Medical News.

UNIVERSITY OF GLASGOW.—At the graduation ceremonial held on Nov. 15th the following degrees were conferred :—

M.D.—Katherine O. Robertson (with commendation), Arthur Anderson, and Alice Cox (in absentia).
M.B., Ch.B.—Isdale Robertson Taylor.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At an ordinary meeting of the Council of the College on Nov. 13th, Sir John Bland-Sutton, the President, in the chair, the Secretary reported the death or Oct. 11th, at the age of 77, of Mr. John Hammond Morgan, M.V.O., F.R.C.S., past member of the Council, and a vote of condolence with his family was unanimously passed.—Mr. Walter G. Spencer was reappointed a member of the Committee of Management of the Conjoint Examining Board.—It was agreed that a reception be held at the College from 4 to 6 P.M. on Wednesday, June 3rd next, for members attending the Interstate Post-graduate Assembly of American Surgeons.—The President reported that Mr. H. S. Pendlebury's term of office on the Court of Examiners would expire on Dec. 10th next, and that the vacancy thus occasioned would be filled up at the ordinary Council on Dec. 11th. Mr. Pendlebury is eligible for re-election.

ROYAL NORTHERN GROUP OF HOSPITALS.—Prince Arthur of Connaught presided over a festival dinner on Nov. 13th at the Hotel Cecil in aid of the Royal Northern Group of Hospitals. In proposing the toast of success to the Northern Hospital, Prince Arthur referred to the greater financial difficulties which confront hospitals in the outer circle of London compared with those of the inner circle. The Royal Northern Hospital with its 387 beds served a population of over one million, and during last year 4030 in-patients were treated and the out-patient attendance numbered nearly 170,000. He appealed to all present to help to clear off the embarrassing debt of £65,000 and put the hospital in a satisfactory financial condition. The Rev. Basil Bourchier supported this appeal in an eloquent speech, in which he spoke of the charitable service this hospital is able to render to the sick and injured of the populous district in which it is situated. Lord Northampton, chairman of the hospital, deplored the fact that the board had been compelled to close 60 beds, with the sad consequence that 1000 patients annually had to be refused admission. The hospital, he declared, is well supported by the residents of Northern London, but wealthy people in the West End, not knowing of the needs of their poorer neighbours, do not give it the support it deserves. He read a letter from Sir Howell Williams offering £20,000 to the hospital in memory of his son Captain Ifor Williams. This generous gift was made on condition that a similar amount should be raised by Jan. 1st, 1925, which should go to the reduction of the debt. In the memorial ward, to the endowment of which Sir Howell Williams has directed his bequest, he wishes that the greater part of the accommodation should be for the people of Islington, and that about six beds should be available for patients nominated by the Welsh community of London. Lord Northampton announced also the receipt of an offer of £3200 for the foundation of a maternity department, provided £5000 were received before the end of the year for the endowment of the department. Sir Arthur Stanley, Mr. H. J. Tennant, Sir Philip Sassoon, and Mr. Malcolm Donaldson also spoke. The donations received at the dinner amounted to over £6650.

A Gift to the Harveian Society of London.—At a meeting of this society held on Nov. 13th at the PaddingtonTown Hall, the President announced the gift by Mr. G. Buckston Browne of £1000 in memory of his only son, Lieut.-Colonel Buckston Browne, D.S.O., who was lost in the war, for the purpose of establishing a Buckston Browne prize. The interest will be used, biennially, after certain deductions for expenses ; the regulations for its award will be submitted to the general meeting in January next. A report of the discussion which took place at this meeting appears on another page.

Medical Candidates for Parliament. — The results of the poll for the constituency of the combined Scottish Universities, which returns three Members, were declared on Nov. 13th. The medical candidate, Sir George A. Berry, was again returned, as was also Sir Henry Craik, who, though not a member of the medical profession, has its interests at heart. The figures were : (1) Cons., 7189 (Sir Henry Craik) ; (2) L., 5010 ; (3) Cons., 3781 (Sir George Berry) ; (4) Lab., 1638. The total number of medical men now entitled to sit in the House of Commons is 12. A list of the other 11 was given in The Lancet of Nov. 8th, p. 987.

Australian and New Zealand Medical Association in England.—The half-yearly dinner of the Association will be held at the Trocadero Restaurant, Piccadilly, on Friday, Dec. 12th, at 7.30 for 8 p.m. Further particulars may be obtained from Dr. E. T. C. Milligan and Dr. H. Bedford Russell, the hon. secretaries, at 86, Harley-street, W. 1.

Medicine and Missions.—At a meeting on behalf of medical missions in connexion with the Society for the Propagation of the Gospel in Foreign Parts, held in the Central Hall, Westminster, on Nov. 12th, Sir Leonard Rogers, who was in the chair, spoke of the good work being done by medical missionaries of various denominations throughout the world, and especially of what he had seen himself. He paid a tribute to valued personal friends among them who had died in harness, such as Dr. Pennell on the North-West Frontier of India ; Dr. Hearn, of the Dublin University Mission in Chota Nagpur. He referred to the large number of patients treated by the missions in connexion with the society in various parts of India, in North China, and in South Africa, and of the importance of the endeavours made by the society to pay its workers a living wage, and to have at least two doctors at every hospital. He pointed out the need for many more workers, especially men. In conclusion, he referred to the new opening for work in all mission hospitals in the tropics for the treatment of leprosy, which could now be carried out more effectively than ever before, especially in its earlier stages. Nearly every case could be relieved of bad symptoms and of infectivity. The result was that large numbers were coming forward for early treatment instead of hiding the disease until it was too late. It had been found that a considerable number of these earlier cases were not infectious, and it was quite unnecessary to isolate them ; hence they could be treated as out-patients in all mission hospitals. Sir Leonard Rogers reiterated his belief that leprosy could be reduced to a negligible quantity.

Advisory Committee on the Welfare of the Blind.—In view of the development in the work among the blind owing to the operation of the Blind Persons Act, 1920, the Minister of Health has reappointed the Advisory Committee on the Welfare of the Blind for a further period of office. The committee has been constituted so as to afford representation to the local authorities concerned with the working of the Act and to voluntary agencies for the blind, as well as to organised blind workers. The following have been appointed members of the committee : Mr. G. H. Roberts (chairman), Mr. P. M. Evans, LL.D. (vice-chairman), Miss W. Bramhall, Alderman W. J. Burgess, J.P., Mr. J. J. Burton, Dr. J. J. Butterworth, D.P.H., Sir Coles Child, Bart., Mr. Herbert Davey, Canon G. H. P. Glossop, Mr. James Graham, Mr. Thomas Holt, Mr. Arthur L. Lowe, Dr. Robert A. Lyster, D.P.H., Mr. G. F. Mowatt, J.P., Mrs. Wilton Phipps, J.P., Dr. H. A. Powell, Rev. P. S. G. Propert, Mr. Ben Purse, and Mr. W. H. Tate, J.P. A representative of the National League of the Blind and a further representative of the local authorities will be appointed later. The committee will advise the Minister on matters relating to the care and supervision of the blind, including any question that may be specially referred to them by the Minister. Mr. F. M. Chapman, of the Ministry of Health, will act as secretary.

Glasgow University Club of London.—A dinner will be held at the Trocadero Restaurant, Piccadilly, on Thursday, Dec. 11th, at 7.30 p.m., Mr. D. M. Cowan, M.P., in the chair. Any Glasgow University men who, though not members of the Club, desire to attend are requested to communicate with the hon. secretaries, 1, Harley-place, N.W. 1.

St. Vincent's Hospital, Dublin.—On Nov. 11th, in the presence of a large company, the Archbishop of Dublin opened the new out-patient department of this hospital. It is some 90 years, our Dublin Correspondent writes, since Mary Aikenhead, the foundress and head of the Sisters of Charity, founded St.Vincent's Hospital, and it has ever since remained under the care of the Sisters of Charity. These ladies have spared no pains to keep the hospital in touch with modern developments of medicine and surgery, and while always fortunate in their selection of a staff, have made sure that their staff should be given adequate equipment for their work. The new department opened last week contains sections for medicine, surgery, ophthalmology, otology and laryngology, gynæcology, dentistry, radiology, pharmacy, and pathology. The cost of the building was some £37,000, the sum being available from a bequest of the late Mr. Charles Lawler. On Nov. 15th the annual dinner of the staff and past students of St. Vincent's Hospital was held in the Shelbourne Hotel, with Mr. J. S. McArdle, senior surgeon, presiding. A very large number of past students and guests were present, among the latter being His Excellency the Governor-General, the President of the Royal College of Physicians, the President of the Royal College of Surgeons. the Chief Justice, and the President of University College, The absence, through illness, of Dr. M. E. Cox, senior physician to the hospital, was regretted by all.

Edinburgh University Club of London.—The 203rd dinner of the club was held on Nov. 12th at the Connaught Rooms, with Sir Harold Stiles in the chair. Some 200 members and their guests were present. The Chairman, who began in reminiscent vein, spoke of the medical work of his father and his grandfather, and recalled the parental warning he had received when commencing his student career in Edinburgh on the evils of billiard-playing. The Edinburgh Medical School, he said, was supreme at the end of the eighteenth and in the early part of the nineteenth centuries ; it was two Edinburgh medical graduates who founded the first school of medicine in America, at Philadelphia, and the first in Canada, McGill school, was started by four Edinburgh men. It was Charles Bell, he said, who infused the scientific spirit of surgery into London. Great progress had been made in Edinburgh since the middle of last century in two lines, first in abdominal surgery, and second in orthopædic surgery. But more money was wanted, and the speaker hoped that by the recent formation of an alumni society funds for further development would be forthcoming. The value of alumni associations, such as exist in America, had not been hitherto realised. The future of every nation depended on the development of science. Dr. H. J. F. Simson proposed the toast of the chairman in a most entertaining speech. A pleasant programme of songs was rendered in the course of the evening by Mr. W. A. Peterkin.

University of Edinburgh Lodge : Installation and Banquet.—The M.W. the Pro. Grand Master, the Right Hon. Lord Ampthill, was present on Nov. 14th at the Installation Meeting of the University of Edinburgh Lodge, No. 2974, which celebrated the twenty-first anniversary of the Lodge. Some 150 Brethren, including a considerable number of Grand Officers, and many distinguished in the craft and medical profession, attended at Freemason's Hall in the afternoon, when W. Bro. M. Burrow Ray, D.S.O., M.D., opened the Lodge. W. Bro. Robert Cathcart Bruce, P.G.D., and W. Bro. Frederick J. McCann, P.P.G.W., Kent, were elected honorary members of the Lodge. The M.W. Pro. Grand Master Lord Ampthill, assisted by the retiring Master, installed W. Bro. D. C. L. Fitzwilliams, C.M.G., M.D., M.Ch., P.Dep.G.D.C., as Master for the ensuing year, and at a later stage the Pro. Grand Master delivered the addresses. The W.M. invested the following officers : I.P.M., W. Bro. M. Burrow Ray, D.S.O. ; Bro. R. H. Martin, S.W. ; Bro. Alastiar MacGregor, J.W. ; W. Bro. W. E. Porter, Treasurer ; W. Bro. G. C. Cathcart, Secretary ; W. Bro. Hugh Phillips, D.C. ; Bro. Moriarty, S.D. ; Bro. MacCormac, C.B.E., J.D. ; W. Bro. McCrae Aitken, A.D.C. ; W. Bro. F. J. McCann, Almoner ; Bro. H. C. Nixon, Organist ; W. Bro. William Wilson, Asst. Secretary ; W. Bro. H. Critchley, I.G. Stewards : W. Bro. G. A. Gordon, Bro. P. Leighton, Bro. Kerr Simpson ; and Bro. P. McLean, Tyler. A banquet was held in the evening at the Imperial Restaurant, Regent-street, W., when Lord Ampthill, responding for the "Grand Officers," alluded to the strength of Freemasonry amongst the medical profession, a profession devoted (he said) to the welfare of mankind and thus closely allied to the principles of the craft.

University of London: *University College.*—Of the 15 entrance scholarships and exhibitions available for award to students entering this College in October, 1925, three are tenable in the Faculty of Medical Sciences only and three are tenable in any of the five College faculties. Most of the scholarships and exhibitions are of the value of £40 a year for three years, but the value of any scholarship or exhibition may be increased by the grant of a supplementary bursary if the circumstances of the scholar or exhibitioner make such a grant necessary. The Bucknill scholarship (medical) is of the value of 160 guineas; the two medical exhibitions are of the value of 55 guineas each.

University College Hospital Medical Society. The annual dinner of this society will be held on Thursday, Dec. 11th, at Gatti's Restaurant, Strand, W.C. Tickets, 10*s.*, may be obtained from Mr. I. H. K. Stevens, hon. secretary.

Dr. W. B. Coulter (Senior Medical Officer) has been appointed an Official Member of the Executive Council of the Presidency of Montserrat.

Lectures on Psychological Medicine.—The eighth course of lectures at the Maudsley Hospital, Denmark Hill, London, S.E., for the Diploma of Psychological Medicine will commence early in January. The lecturers will be Sir Frederick Mott, Dr. F. Golla, and Dr. Henry Devine.

Irish Medical Schools and Graduates Association.—The autumn gathering and dinner of this association will take place at Pagani's Restaurant, Great Portland-street, London, W., on Nov. 25th at 7.30 P.M. The chair will be occupied by the President, Dr. William J. Corbett. Tickets (10*s.*) may be obtained from Dr. Holmes Meyrick, 48, Ennismore-gardens, London, S.W. 7.

The Parliamentary Secretary to the Ministry of Health, Sir H. Kingsley Wood, M.P., has appointed Mr. E. S. Hill to be his private secretary; the Permanent Secretary to the Ministry of Health, Sir Arthur Robinson, has appointed Mr. R. Stanton to be his private secretary; and the Second Secretary to the Ministry of Health, Sir A. V. Symonds, has appointed Mr. T. H. Sheepshanks to be his private secretary.

Cremation in Manchester.—At the thirty-fourth annual meeting of the Manchester Crematorium, Limited, it was stated that the number of cremations in the last five years had been as follows: 219 in 1920, 211 in 1921, 208 in 1922, 222 in 1923, 234 in 1924. Since the opening of the crematorium in 1892 the total number of cremations has been 4080. The total number in Great Britain for the year ended with August last was 2349, against 1923 in the preceding year.

Rontgen Society.—A meeting will be held on Dec. 2nd, at 8.15 P.M., in the British Institute of Radiology, 32, Welbeck-street, London W., when Prof. J. A. Crowther will read a paper on Some Experiments with Induction Coils, and, jointly with Mr. R. J. Stephenson, a paper on the Effect of Capacity on the Induction Coil. The Council has decided to present the "Rontgen Award for the Session 1923–24" to Mr. L. H. Clark, M.Sc., Physics Department, Middlesex Hospital, who contributed the following papers to the society during the session: (1) A Clinical X Ray Balance Radiometer, (2) On the Measurement of X Ray Intensity.

The late Dr. R. N. West.—General regret has been caused in the district of Manchester in which he practised, Chorlton-cum-Hardy, by the death from pneumonia on Nov 1st of Robert Newberry West, a son of the late Rev. J. R. O. West, Canon of Manchester. Dr. West studied at Owens College and graduated M.B. and Ch.B. at the University of Manchester in 1901. He served for four years on active service in France as a captain in the R.A.M.C. He was district medical officer and public vaccinator in his town to the Chorlton Union, and was prominently identified with the St. John's Ambulance movement. He leaves a widow and one child.

Hospital for Epilepsy and Paralysis.—The committee of management of the Hospital for Epilepsy and Paralysis, Maida Vale, London, W., has placed the facilities of the pathological, X ray, and Swedish remedial departments at the disposal of medical practitioners for the benefit of patients who are not in a position to pay the usual charges. The pathologist is Dr. Douglas McAlpine, M.R.C.P., an honorary assistant physician of the Hospital who is acting as honorary pathologist until the use of the laboratory justifies the appointment of a full time paid pathologist. The biochemist is Mr. Hugh Nichol, M.Sc., who until the work demands it will also do the bacteriology. A schedule of charges has been issued in which, for instance, the Wassermann test is 15*s.*, a section of tumour with report or a blood-sugar estimation 10*s.* 6*d.*, X ray of bismuth meal £5 5*s.*, supervised Swedish exercise 5*s.* for half an hour. In accordance with the principles of the hospital these payments will be voluntary and may be reduced on the recommendation of a practitioner to meet the needs of individual patients. All communications should be addressed to the secretary of the hospital.

Donations and Bequests.—Mr. William Byrom, cotton spinner, late of Heaton Mersey, who left £32,569 after the payment of small legacies, gave the whole of his estate to charitable institutions, including £720 to the National Children's Home and Orphanage founded by the late Dr. Stephenson; £480 each to Dr. Barnardo's Children's Home, United Kingdom Alliance, Victoria University, Manchester; Manchester and Salford Sunday Fund, and Manchester Royal Infirmary; and £240 to Mauldeth Hospital for Incurables.—Mr. John Drake, of Halifax, who left £3148 after personal bequests, left the residue of the property to the Society for the Home Teaching and Assistance of the Halifax Blind.—Mr. William Stones, Manchester, mineral water manufacturer, left estate of the gross value of £172,375. After the fulfilment of legacies and failing certain trusts, he left the ultimate residue of his property as to—three-tenths to the Manchester Royal Infirmary and Dispensary; one-fifth to St. Mary's Hospital, Manchester; and one-fifth to the Manchester Children's Hospital; one-tenth to the Manchester Eye Hospital; one-tenth to the Northern Counties Hospital for Incurables, Mauldeth; one-tenth between the Christie Hospital and the Manchester and Salford Hospital for Skin Diseases.—The Royal Manchester Children's Hospital has received £1000 from H. Pownall to endow "The Anne Pownall Cot" and £740 from the Manchester Corporation.—On Oct. 18th the thanks of the Senate of the University of Cambridge were accorded to Mr. Ernest H. Gates, who has provided the necessary sum to enable the University to accept the offer made by the Trustees of the Rockefeller Foundation for the endowment of the School of Pathology; and to the Rockefeller Trustees for the endowment of the School of Pathology.—Sir George Wills has given £60,000 for the purpose of erecting a new nurses' home and a new out-patient and casualty department at the Bristol General Hospital.—Two anonymous donors have given £15,000 to the Northampton General Hospital for additional apparatus and equipment for the electrical department, and the chairman of the institution, Mr. R. B. Loder, has made a donation of £300.—Mr. George Tilling, solicitor, Streatham, left £200 each to the Royal Microscopical Society, the Quekett Microscopical Club, Guy's Hospital, Dr. Barnardo's Homes, the British Red Cross Society.—Mr. Alfred Hargreaves, of Woodlands, near Keighley, left £250 each to the Keighley and District Victoria Hospital and the Skipton and District Hospital, payable on the death of his wife.—Mr. Robert Hesilrige Buckby, solicitor, Syston, gave on the death of his wife £100 each—amongst other institutions—to the Leicester Institution for the Blind, the Leicester Royal Infirmary, the Middlesex Cancer Hospital, the Institution for the Deaf and Dumb, Derby, the London Female Guardian Society, and the Ragged School Union.—Sir Samuel Turner, an ex-mayor of Rochdale and asbestos manufacturer, besides other charitable bequests, left £4000 to the National Children's Home and Orphanage, with the request that it be used for the erection of an additional home for orphans; £3000 to the Rochdale Infirmary for the endowment fund; £1000 to the Rochdale Nursing Association for the endowment fund; £1000 to the Rochdale Crippled Children's Union for the endowment fund; and £500 to the Rochdale and District Society for Visiting and Instructing the Blind, for the endowment fund.—Mr. Richard Baron, of Lower Darwen, bequeathed £500 each to the Blackburn Infirmary and to Blackburn Ragged School.—Dame Florence Emily Fermor-Hesketh, Roehampton, left £40,000 for such charitable institutions and objects in California as her executors may think fit and £10,000 for similar purposes in England.—Towards the Lord Mayor's Hospital Fund in Leeds the Leeds National Health Insurance Committee has contributed £1000 and the town of Pudsey £2641, thereby establishing a record for itself.—Alderman William Henry Churton, solicitor, of Chester, left £200 to the Chester Royal Infirmary.—Mrs. Millicent Salting, Berkeley-square, W., left £2000 each to the Middlesex Hospital, St. Mary's Hospital, Paddington, and the Cancer Hospital, Fulham-road, S.W.; £1000 each to the Brompton Hospital for Consumption and King's College Hospital.—Miss Annie Webster, Headingley, Leeds, left £1000 to the Leeds General Infirmary to endow an "Annie Webster Bed."—Dame Edith Annie Armstrong, of Pangbourne, Berks, left £1050 to the Royal Northern Hospital, Holloway-road, N., "for a Jack Armstrong bed in proud and dear memory of my son who fell gloriously for King and Country, Jan. 25th, 1915."—The Chelsea Hospital for Women has received an Armistice Day donation of £200.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Nov. 24th.

ODONTOLOGY: at 8 P.M.
Paper:
Mr. G. J. Goldie and Prof. Collingwood: A Note on Protagulin in Hæmorrhage after Extraction.

Tuesday, Nov. 25th.

MEDICINE.
No meeting of the Section of Medicine will be held in November.

Wednesday, Nov. 26th.

COMPARATIVE MEDICINE: at 5 P.M.
Paper:
Mr. Leslie Pugh: Puerperal Septicæmia in Cattle.
A discussion will follow, opened by Prof. Louise McIlroy.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.
Members of this Section are specially invited to attend the above meeting.

ANNUAL DINNER OF THE SOCIETY: Hotel Victoria, 7.30 for 8 P.M.

Thursday, Nov. 27th.

BALNEOLOGY AND CLIMATOLOGY: at 4.30 P.M.
Presidential Address:
Dr. W. Edgecombe: The Principles of Spa Treatment in Great Britain.
To be followed by a discussion.

EPIDEMIOLOGY AND STATE MEDICINE: at 5.30 P.M.
Paper:
Dr. T. Carnwath: A Brief Survey of Public Health Organisations in the United States of America.

UROLOGY: at 8.30 P.M.
Clinical and Pathological Evening:
Members wishing to show cases or specimens are requested to notify the Hon. Secretary (Mr. S. G. MacDonald, 51, Queen Anne-street, W.) without delay.

Friday, Nov. 28th.

STUDY OF DISEASE IN CHILDREN: at 4.45 P.M.
Clinical meeting at St. Thomas's Hospital, S.E.

BALNEOLOGY AND CLIMATOLOGY.
It is hoped to arrange for a visit to some orthopædic institution. Particulars to be announced later.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
Monday, Nov. 24th.—8.30 P.M., Discussion on the Treatment of Senile Gangrene, to be introduced by Sir Anthony Bowlby, Bart., K.C.B., followed by Dr. Harold A. Des Vœux, Mr. Sampson Handley, and others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.
Monday, Nov. 24th, to Saturday, Nov. 29th.—West Lecture Hall, Royal Society of Medicine, 1, Wimpole-street, W. Lecture arranged by the Fellowship of Medicine, and open to all members of the profession. At 5.30 P.M., Monday, the 24th inst., Mr. Victor Bonney: Cancer of the Uterus.—Chelsea Hospital for Women, Arthur-street, S.W. Special Course in Gynæcology, consisting of lectures, demonstrations, and operations.—Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynæcology. Lecture-Demonstrations in the wards and out-patient departments.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith.
Monday, Nov. 24th.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
Tuesday.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.
Wednesday.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept. 4.30 P.M., Dr. Trevor Davies: Gynæcological Demonstration.
Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 11 A.M., Mr. Simson: Gynæcological Wards. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.
Friday.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.
Saturday.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Tuesday, Nov. 25th.—4.30 P.M., Mr. T. H. C. Benians: Blood-Sugar and Blood-Urea in Diagnosis and Treatment.
Friday.—4.30 P.M., Mr. H. W. Carson: The Methodical Investigation of Stomach Cases.
Daily: Medical and Surgical Clinics, Clinics in the various Special Departments, Surgical Operations, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Thursday, Nov. 27th.—4 P.M., Mr. Tyrrell Gray: Acute Peritonitis.

ROYAL DENTAL HOSPITAL OF LONDON POST-GRADUATE LECTURES.
Wednesday, Nov. 26th.—5 P.M., Mr. T. B. Vaile: Some Points in Anæsthesia for Dental Cases.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
Tuesday, Nov. 25th.—5 P.M., Dr. A. M. H. Gray: Bacterial Affections.
Thursday.—5 P.M., Dr. Haldin Davis: Seborrhœa. Seborrhœic Dermatitis.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
Monday, Nov. 24th.—(At the Children's Hospital.) Mr. Dun: Surgical Cases.
Tuesday.—(At the Southern Hospital.) Mr. Leyland Robinson: The Disorders of the Menopause.
Wednesday.—(At the Northern Hospital.) Dr. Pemberton: Arthritis Deformities.
Thursday.—(At the Stanley Hospital): Miss Ivens: The Diagnosis and Treatment of Uterine Fibroids.
Friday.—(At the Royal Infirmary.) Mr. Kelly: Surgical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
Tuesday, Nov. 25th.—4.15 P.M., Mr. P. R. Wrigley: The Place of Splenectomy in Surgery.
Friday.—4.15 P.M., Mr. A. H. Burgess: Some Points in the Surgery of the Biliary Tract.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES. (At 3.30 P.M.)
Tuesday, Nov. 25th.—(At the Royal Infirmary.) Dr. Yates: Pathology as a Basis of Treatment in Some Common Diseases.
Friday.—(At the Royal Hospital.) Dr. P. Hay: Miners' Nystagmus.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.
Wednesday, Nov. 26th.—3.15 P.M. (at the Town Club, Swindon). Dr. O. C. M. Davis: Defective Dietary as a Cause of Children's Disorders.

ROYAL INSTITUTE OF PUBLIC HEALTH, Russell-square, W.C.
(Course of Lectures on the Health of the Commonwealth.)
Wednesday, Nov. 26th.—4 P.M., Prof. Winifred Cullis: The Practice of Health.

ROYAL ANTHROPOLOGICAL INSTITUTE.
Tuesday, Nov. 25th.—8.30 P.M. (in the Lecture Room of the Royal Society, Burlington House, W.) Prof. Dr. R. Verneau: La Race de Neanderthal et la Race de Grimaldi: Leur Rôle dans l'Humanité. (Huxley Memorial Lecture.)

THE ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.
Tuesday, Nov. 25th.—4 P.M., Dr. Hynd: The Chemical Constitution of the Urine and Blood in Health and Disease.

CHADWICK PUBLIC LECTURES.
Wednesday, Nov. 26th.—5.15 P.M. (at the Medical Society's Rooms, 11, Chandos-street, W.). Dr. W. W. Feldman: Antenatal Physiology and Hygiene.

THE PEOPLE'S LEAGUE OF HEALTH. Course of Lectures on the Mind and What We Ought to Know About It.
(At the Medical Society of London, 11, Chandos-street, W.)
Monday, Nov. 24th.—6 P.M., Sir Frederick Mott: Mind and Body.

Appointments.

Cooke, Robert Hunt, M.B., B.S. Lond., has been appointed Medical Registrar, Hospital for Epilepsy and Paralysis and Other Diseases of the Nervous System, Maida Vale.

Payne, Alfred Ernest, M.B. Lond., M.R.C.S., L.R.C.P. Lond., Honorary Radiologist, Leicester Royal Infirmary.

Surgeons under the Factory and Workshop Acts: Ness-Walker, J., M.R.C.S., L.R.C.P. Lond., Castleton; Bates, K. L., L.R.C.P. Lond., M.R.C.S., St. Albans; Richards, W. K. A., M.B., Ch.B. Bristol, Westbury; and Arthur, J., Wellingborough.

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth Infirmary, &c.—H.S. £200.

Barrow-in-Furness, North Lonsdale Hospital.—Two H.S.'s. Each £175.

Birmingham City Tuberculosis Dept.—Asst. M.O. £450.

Brighton, New Sussex Hospital for Women and Children.—Hon. Radiologist.
Bristol City and County of Education Dept.—Asst. Sch. M.O. £600.
Bristol General Hospital.—Hon. Clin. Assts.
Bristol Royal Hospital for Sick Children and Women.—Hon. P. to Out-patients.
City of London Maternity Hospital, City-road, E.C.—Res. M.O. at rate of £100.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Anæsthetist. £50.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. S.
Exminster, Devon Mental Hospital.—Jun. A.M.O. £300.
Gordon Hospital, Vauxhall Bridge-road, S.W.—Res. H.S. at rate of £75.
Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—H.P., and H.S. Also Cas. Med. O. and Cas. Surg. O. All at rate of £100.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Ophth. S.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each £50.
London Lock Hospital, 91, Dean-street, W.—Clin. Assts.
London Temperance Hospital, Hampstead-road, N.W.—R.M.O. at rate of £175.
Manchester, Eccles and Patricroft Hospital.—H.S. £200.
Manchester Hospital for Consumption, &c., Bowden, Cheshire.—R.M.O. £200.
Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—Sen. and Jun. H.S. £130 and £100 respectively.
Manchester Royal Infirmary.—Hon. Asst. Radiologist.
Metropolitan Ear, Nose, and Throat Hospital, Fitzroy-square, W.—Asst. S. and Clin. Assts.
Ministry of Health, Whitehall, S.W.—M.O. £600 and bonus.
Oxford, Radcliffe Infirmary and County Hospital.—H.S. and Obstet. H.P. Each at rate of £120.
Park Royal Hospital, Acton Lane, W.—Res. Asst. M.O. £350, bonus, &c.
Poplar Hospital for Accidents, East India Dock-road, E.—Hon. Dent. S.
Prince of Wales's General Hospital, N.—Clin. Assts.
Reading, Royal Berkshire Hospital.—Hon. Asst. S.
Rotherham Hospital.—Hon. Radiologist.
Royal Army Medical Corps.—Commissions.
Royal Eye Hospital, St. George's-circus, S.E.—Jun. H.S. £100.
Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £150. Cas. O. £100. Asst. Cas. O., Obstet. Asst. £50. Obstet. H.S. H.P. and H.S. Also Surg. and Gynæcological Reg. £250.
Royal London Ophthalmic Hospital, City-road, E.C.—Pathologist and Curator. £200.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. at rate of £100.
Sheffield University.—Asst. Pathologist. £500.
Somerset County Council, Quantock Lodge Tuberculosis Sanatorium.—Res. Med. Supt. £739 12*s.*
Truro, Royal Cornwall Infirmary.—H.S. £170.
Virol Scholarship in Hæmatology. £200.
West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Asst. P., Laryngologist. Also Otologist.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Non.-Res. H.S. at rate of £150.
Windsor, King Edward VII. Hospital.—Jun. H.S. At rate of £100.

Births, Marriages, and Deaths.

BIRTHS.

PATTERSON.—On Nov. 8th, at Bedford, the wife of Surgeon-Commander T. C. Patterson, R.N., of a son.

TRAVERS.—On Nov. 13th, at Phillimore-gardens, W., the wife of Dr. Ernest Travers, of a son.

MARRIAGES.

RISIEN-RUSSELL—CLEMENT.—On Nov. 17th, in London, J. S. Risien-Russell, M.D., F.R.C.P., of Wimpole-street, W., to Ada Clement, daughter of the late Wilkinson Hartley, Esq., J.P., C.A., and Mrs. Wilkinson Hartley, J.P., of Carr Hall, Nelson, Lancashire.

DEATHS.

BURROWS.—On Nov. 13th, in a nursing home, Cambridge, Cresswell Burrows, M.A., B.Sc., M.D. Camb., M.R.C.S. Eng., L.R.C.P. Lond.

LEE.—On Nov. 17th, at West Drayton, Robert James Lee, M.B., M.D. Camb., aged 84.

LONG.—On Nov. 16th, at Micklegate, York, David Sanderson Long, M.D.

MATTHEWS.—On Nov. 13th, at Strathyre-avenue, Norbury, S.W., Dr. J. Sydney Matthews, M.R.C.S., L.R.C.P., L.M.S.S.A. Lond., of Cape Town and London.

PALEY.—On Nov. 12th, at Brunswick-place, Hove, Brighton, of heart failure following operation, Frederick John Paley, M.D., aged 65 years.

POWELL.—On Nov. 5th, accidentally drowned at sea, James Farquharson Powell, M.C., M.R.C.S., L.R.C.P., of Boscobel-road, St. Leonards-on-Sea.

TAYLOR.—On Nov. 14th, at Eaton-hill, Norwich, Sidney Johnson Taylor, M.D., aged 67.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

PUBLIC HEALTH IN TANGANYIKA.

A REPORT on the Mandated Territory of Tanganyika for the year 1923 has been issued from the Colonial Office for the information of Parliament. The Territory consists of that portion of the former colony of German East Africa which, under the Treaty of Peace with Germany, it was agreed should be administered under a mandate by His Britannic Majesty. It extends from the Umba River on the north to the Rovuma River on the south, the coast-line being about 500 miles in length, and includes the adjacent islands. The total area is about 365,000 square miles. Along the coast lies a plain, varying in width from 10 to 40 miles, behind which the country rises gradually to a plateau constituting the greater part of the hinterland. This plateau falls sharply from a general level of 4000 feet to the level of the lakes (Tanganyika, 2590 feet; Nyasa, 1607 feet), which mark the great Rift Valley extending northwards to Lake Naivasha. The seat of Government is Dar-es-Salaam (population approximately 25,000), a modern town founded in 1862 by the then reigning Sultan of Zanzibar and subsequently occupied by the Germans in 1887. The highest parts of the Territory are in the north-east, where are the extinct volcanoes, Kilimanjaro, which rises to 19,720 feet and is snow-capped, and Mount Meru (14,960 feet). In the south-west are the Livingstone Mountains, where the highest peak is over 9000 feet. The population of the Territory, according to the latest census (1921), was as follows: Europeans 2447, of whom 1598 were British subjects; Asiatics 14,991, of whom 9411 were Indians, 7987 Goans, and 4782 Arabs; natives 4,107,000. The European population is composed of officials, planters, merchants, and employees of business firms and estates, while Indians and Goans find occupation as shopkeepers, clerks, and artisans.

Infectious Disease.

Epidemics.—In 1923 the Territory was remarkably free from epidemics, and the general health compared favourably with previous years; plague and small-pox showed a diminished incidence, while there was only one outbreak of cerebro-spinal fever of any importance; they occurred in a few villages on the shores of Lake Victoria, east of Mwanza, where 90 cases with 82 deaths were reported. Early in the year epidemic *influenza* broke out in the south-western area. The type of disease was not severe; the epidemic was always well in hand, and was completely stamped out by the end of the year. Influenza of a more severe type broke out in the neighbourhood of Singida during November, but energetic measures were instituted, and the disease did not spread to the surrounding districts. There were 33 deaths during the year from small-pox, 89 from cerebro-spinal fever, 26 from plague, and 291 from influenza. In addition there were several outbreaks of minor infectious diseases such as chicken-pox and mumps.

Trypanosomiasis.—Cases of sleeping sickness continued to occur in the Mwanza district, 49 cases being diagnosed during 1923 as compared with 92 in 1922. The removal of the natives from the neighbourhood of the forest appears to have checked the disease in the Sultanates of Itilena, Sengerema, and Usmao, but in the Ntusu district, where the removal was not so thoroughly carried out, 22 were discovered. It seems certain that infection is acquired by the natives when visiting the tsetse-fly forest to cut poles, make rope, and for other purposes. The disease has shown no tendency to assume true epidemic proportions, and a violent outbreak need not be apprehended. The principal medical officer visited the area in September and October, and took with him a supply of Bayer "205," but it is too early as yet to give any definite opinion as to the results of the treatment with this drug, though the reports received to date are encouraging.

Venereal Disease.—Until a medical survey can be made, and continuous travelling undertaken by medical officers, the extent of venereal disease can only be estimated so far as the towns are concerned. Many of these are without doubt heavily infected, and in the Bukoba jail it was found that over 50 per cent. of the male prisoners and 25 per cent. of the females were syphilitic. Many natives present themselves for treatment, but cannot be persuaded to continue to attend until they are properly cured. In the country districts where estimates of prevalence have been based in the past on non-professional opinion, it is probable that the extent of venereal disease has been greatly exaggerated, and that laymen have frequently diagnosed as syphilitic symptoms which are certainly those of yaws, a disease which is known to be widespread throughout the Territory, while even leprosy is mistaken for it. It was found that on the medical examination at the Tabora hospital of 2000 or 3000 recruited by private employers during the year, less than 1 per cent. showed infection of venereal disease, while at Pagani hospital only 36 cases were found amongst 2300 natives treated during the year. In Mwanza district, which had always been considered one of the centres of the disease, the medical officer reports that it is no more common than in most East African towns. Evidence supports the view that its prevalence in the country, apart from the townships, has been magnified, and that tribal custom is the main bulwark against its spread. The formation of relationships between the women of the tribe and strangers leads to abandonment of family ties, to the loss of the marriage dowry by the parents, and of potential man-power by the community, so that, while no great importance is attached to intercourse before marriage so long as this takes place with members of the tribe, public opinion discourages promiscuous relations with aliens. There are, of course, tribes whose moral laxity is more pronounced, and it is among these that the disease is spread by itinerant native leaders from the towns, who are generally carriers of infection. The dangers of the disease and of its sequelæ are constantly being brought to the notice of the natives, and in the Mwanza and Tabora districts pamphlets have been distributed.

The Treatment of Yaws.—A great step forward in the treatment of yaws was achieved by the adoption of bismuthotartrate of potassium and sodium as a substitute for higher arsenical preparations such as neo-salvarsan, &c., which were hitherto regarded as specifics for the disease, but were so expensive that their employment on a large scale was hardly possible. An account of the successful treatment of syphilis by bismuth at the Pasteur Institute in 1922 led the deputy principal medical officer, Dr. Shircore, to test its value in the treatment of yaws, when it was found that even advanced cases were cleared up and apparently cured within a few days. The cost of this drug, which in the first instance was prepared locally (and which still is in Kenya), is very small, working out approximately at a penny for ten doses, as against 6*s.* for a dose of neo-salvarsan; for a small sum it should, therefore, be possible to initiate a campaign against the disease, and, by means of travelling dispensaries working systematically over the country, largely to eliminate it.

Malaria is common throughout practically the whole Territory, and the mountainous areas in the north-east and south-west are the only districts where the danger of infection is not constantly present.

Medical Arrangements.

Medical examination of all recruited labour prior to engagement is insisted on and the health of the workers has been good. Residence on coast seems to have no ill-effect on the native from the highlands, but, on the other hand, the inhabitants of low-lying districts who proceed to high altitudes are extremely liable to pulmonary complaints which often prove fatal. For this reason requests from Arusha and Moshi to recruit labour from the Lake Victoria districts were refused after consultation with the medical authorities. The missions accomplish much valuable medical work among the natives, and include among their personnel four medical practitioners, several nurses, and a number of members who have received some training in medical and nursing work. Some of the large sisal estates have a dispensary and a small hospital ward for sick natives on their plantations, where medical attention is provided in minor ailments, the more serious cases being sent in to the nearest Government hospital. For the year ending March 31st, 1923, the expenditure on the medical department amounted to £90,000; for 1923–24 £104,000 were approved, while £116,000 have been granted for 1924–25, but even these increases do not permit of the extension which is desirable and necessary. State medical services are at present confined to the Government hospitals and dispensaries where natives come for attendance, while only in the more important centres is it possible to station European medical officers; and though the missions cover a wide field in the districts, much remains to be done. Medical salaries are on the whole more generous than those of other departmental officers, but it is difficult to obtain suitable candidates as medical officers, and the shortage was so severe that for part of the year there was no European doctor between Dar-es-Salaam and Tabora.

Climate.

The climate of Tanganyika Territory varies greatly according to the height above sea-level of the several districts. Roughly, four climatic zones can be distinguished, though even among these there are considerable local variations. (1) The warm and rather damp coast region with its adjoining hinterland. Here conditions are tropical though not unpleasant, except just before and during the rainy seasons, when the heat is trying and the atmosphere humid. The average yearly temperature is 78°. (2) The hot and moderately dry zone between the coast and the central plateau (300 feet to 2000 feet). This zone is characterised by low humidity of atmosphere, less rain, and a temperature rather lower but with greater daily and yearly variations. (3) The hot and dry zone of the central plateau between 2000 feet and 4000 feet in height. The climate of this zone differs, of course, greatly in parts, but its prevailing characteristics are low humidity, little rainfall (at Tabora an annual average of 32 inches), a fairly high mean temperature. The heat is dry and not so trying to the European as the moist and steamy warmth of the coast, while the nights are invariably cool. (4) The semi-temperate regions around the slopes of Kilimanjaro and Meru, of the Usambara highlands, the Ufipa plateau and the mountainous areas of the south-western area (5000 feet to 10,000 feet). Frosts occur at the higher altitudes and the nights are cold. These districts enjoy a bracing climate, and alone can be considered healthy for Europeans. There are two well-defined rainy seasons annually. Generally speaking, the long rains begin in February or March and last for two or three months, while the short rainy season extends from October to November, but the rainfall is low for a tropical country and droughts are not infrequent.

HEALTH CONDITIONS IN GOLD COAST COLONY.

THE report on the Blue-book for 1922–23, signed by Mr. W. H. Gilliland, Assistant Colonial Secretary, states that the population of the Gold Coast and its Dependencies, as taken in the Census of 1921, was 2,078,043. The number of Europeans resident in the colony during 1922–23 was 2998, composed of 979 officials, 1410 engaged in mercantile pursuits, 521 engaged in mining, and 88 missionaries. In the 17 registration areas there were recorded during 1922–23, 2988 births, 149 stillbirths, and 3283 deaths, Europeans being included in these figures. The number of births registered exceeded all previous records, but is still below the actual figure, as birth registration continues to be very unpopular amongst the uneducated classes. The figure for deaths is approximately accurate as no burial permits are granted without registration. Pulmonary and intestinal diseases are again the principal causes of death. An analysis of the death and invaliding statistics of the European population is appended:—

1922–23.	Number of residents.	Deaths.	Invalided.	Death-rate per 1000.	Invaliding-rate per 1000.
Officials ..	979	6	30	6·12	30·64
Merchants ..	1410	19	29	13·47	20·56
Mining companies	521	5	15	9·59	28·79
Missionaries.	88	1	2	11·36	22·72

The six deaths amongst European officials were due, one each, to the following causes: hyperpyrexia, compound comminuted fracture and septicæmia, blackwater fever, yellow fever, dysentery, and encephalitis. Of the 25 deaths amongst European non-officials, 5 were due to yellow fever, 6 to blackwater fever, and one each to malaria, unclassified fever, enteritis, syncope, pulmonary tuberculosis, intestinal obstruction, cut-throat, fractured skull, septicæmia, heart failure, meningitis, mitral disease, fatty degeneration of the heart, and cancer. Treatment was given during the year in 7506 cases of malaria, 908 of dysentery, 22 of yellow fever, 599 of pneumonia, 385 of tuberculosis, and 1 of plague. Fifteen cases of sleeping sickness were also treated. Of 48 cases of blackwater fever 6 proved fatal, and of 18 definite cases of yellow fever 13 resulted in death. The climate, though hot and damp, is cooler than that of most tropical countries situated in the same latitude. It is not in itself unhealthy, but an evil reputation has been earned for it in the past by the prevalence of mosquito-borne diseases, against which all possible precautions have constantly to be taken. The Gold Coast is peculiarly free from many of the discomforts associated with tropical countries. The efforts of the medical and sanitary authorities in promoting the treatment of disease and the knowledge of general hygiene continue to exercise a beneficial effect on the general health of Europeans. The rainfall varies with the configuration of the country, and is highest in the mining districts of Tarquah, Upper and Lower Wassau, &c., and also at Axim. The first rains, or rainy season proper, begin in March and end in July; the later rains are spread over the months of September and October. The rainy season is marked by a considerable fall in the temperature. The Harmattan season begins in December and ends in February. The rainfall in inches in 1922–23 was 26·53 in Accra, 52·32 in Aburi, 50·66 in Seccondee, 65·42 in Axim, 62·23 in Tarquah, 65·25 in Coomassie, and 38·48 in

Tamale. At Accra the mean shade temperature for the year was 80·0° F. At Coomassie and Seccondee it was 78·9° and 79·3° respectively. The mean daily range of temperature in Accra was 16·9°.

THE HEARSON CAPSULE.

THE connexion between a poultry-farmer in Surrey, a bacteriologist in his laboratory, and a club steward serving ice-cold drinks in the tropics, may sound remote enough to please the most fastidious student of detective fiction. The Hearson capsule, however, supplies this link: it is employed nowadays to regulate incubators, bacteriological or otherwise, and in a modified and extended form for regulating high and low temperatures. It is, therefore, of invaluable assistance both to the bacteriologist, although forming an almost insignificant part of his apparatus, and also to the club steward who wants to keep his drinks in a cool place where the beer will not freeze solid. The poultry-farmer also wants his incubators at a constant temperature, and 40 years ago the late Mr. Charles Hearson was approached by a friend who kept a farm in Surrey and who was making tentative experiments on the artificial incubation of eggs. He was finding it difficult to keep his primitive apparatus, consisting of a large box surrounded by a water-jacket, at a constant temperature. His difficulties appealed to Mr. Hearson, who shut himself up in a room at the top of a house in South London and worked until he had discovered the thermostatic capsule which bears his name. All this is told in the introduction to the latest catalogue of the well-known firm of Chas. Hearson and Co., Ltd. The Hearson capsule consists essentially of a narrow chamber formed by sealing together two flat pieces of metal. Into this chamber is introduced a small quantity of fluid, the boiling-point of which is near the temperature which it is desired to maintain. When this temperature is reached the fluid boils and the capsule expands moving a lever which cuts off the supply of heat. A large range of temperatures can be provided for by choosing suitable fluids, while for very high or low temperatures a different principle is involved. Such was the starting point for the manufacture of the modern incubator and the Hearson capsule can be employed for regulating the supply of heat by oil-lamps, gas, or electricity. It sounds very simple, but it is "the secret of the completion of the capsule"—that is, the sealing-off of the metal chamber—"which has enabled the Hearson Company to defy all competition."

UNITED HOSPITALS WINTER SPORTS CLUB.

To the Editor of THE LANCET.

SIR,—I trust that you will assist me once again to bring this club to the notice of your readers. It was founded to obtain advantageous terms at winter sport resorts and to encourage these sports amongst past and present students of all recognised medical schools in the United Kingdom. This year the Lord Dawson Cup for Ski-ing will be competed for early in January at the Club Hotel at Griesalp, Bernese Oberland; but for those members who prefer the Engadine a second hotel at Sils-Maria (45 minutes' drive from the station at St. Moritz) has undetaken to assist our members in many ways. Full particulars can be obtained from the manager of the Grand Hotel, Griesalp, Bernese Oberland, and from the manager of the Hotel Waldhaus, Sils-Maria (Engadine). I am, Sir, yours faithfully,

J. DUNCAN LYLE, Hon. Sec.

Maidenhead, Nov. 14th, 1924.

NATIONAL BABY WEEK COUNCIL.

AT a meeting of the Council held at Carnegie House on Nov. 12th Dr. T. Watts Eden spoke on the relation of antenatal care to maternity and child welfare. He suggested three main reasons why expectant mothers should receive supervision: (1) While the reaction and disturbance caused by pregnancy varied enormously in different cases, the margin of health was always a narrow one, and medical care was desirable. (2) Some of the most serious emergencies connected with child-bearing gave warning by premonitory symptoms. The classic example of eclampsia was nearly always preceded by albuminuria, which could be detected by skilled attention and the fits averted. (3) Difficulties likely to arise during the birth process, such as narrowing of the passage or faulty position of the child, could be discovered and dealt with satisfactorily before the birth process began. Antenatal work might influence the unborn infant through environment, using that word in a broad sense. Certain infectious diseases could be transmitted from the mother to the child, and some organic diseases might render the placenta incapable of carrying on its work, when the life of the child would come to an end. Nervous disturbance affected the chemical composition of the blood and the bodily secretions, and would influence the fluids supplied by the mother to the infant. Peace and quiet was one of the greatest needs of the expectant mother; the child of a nervous mother was subject to the influence of a nervous environment while still in the uterus.

Miss Hester Viney, speaking of the difficulty of antenatal work among village mothers, alluded to their complete ignorance of physiology. A woman who did not even know she had a pelvis would not be impressed by information concerning her pelvic measurements. A scheme by which a higher fee was charged for late booking with doctor or midwife had proved helpful in getting earlier into touch with patients. In rural districts antenatal work usually grew out of the welfare centre. Mr. E. B. Turner, F.R.C.S., said that propaganda was more difficult among fathers than among mothers. Men did not realise the strain their wives were subject to in child-bearing, and were neglectful from want of knowledge rather than want of heart. Health films could be made both attractive and educational; antenatal centres should be held for fathers as well as mothers, and they should be taught about diseases from which they might suffer and which might affect their wives. The medical curriculum now entailed attendance at welfare centres, so that young medical practitioners were better instructed in matters of maternity and child welfare than formerly. A ten minutes' film on the work of a welfare centre was shown after the meeting, giving a good idea of the routine activities of the centre. The action of the kinema unfortunately produced its curious atmosphere of intense rapidity, especially marked in the scenes of the doctor's consultation. This slightly modified the otherwise entirely useful effect of the pictures.

A NEW SUN RAY ARC LAMP.

THE Westminster Engineering Company has recently produced a new sun ray arc lamp which, it is claimed, gives a light of great intensity, rich in ultra-violet rays and also in luminous and heat rays. The lamp contains special large white-cored carbon electrodes which burn with a long flame with about 90 volts across the arc and they will last for seven to eight hours without attention. Both carbons are automatically adjusted so that the point of focus of the arc remains fixed. The lamp is made to work with either an alternating or a direct current, and in the forme case a choking coil is included in the apparatus. An easil worked control board enables resistance to be introduced into the circuit if necessary, and the lamps are made fo the ordinary circuits of 220/250 volts and 100/120 volts the arc takes about 25 amperes, and two or more can b arranged in series. The arc can be hung from a roof-rai and appears to be particularly valuable for the applicatio of the general arc light bath. According to the results o certain investigations the light from this arc is stated t contain the heat, visible and the longer ultra-violet rays and is comparable to sunlight. Many institutions are now installing arc lamps, for the tendency in this country is t rely upon artificial sources for "sunlight," and the "Westminster-Eidinow" lamp is already deservedly popular It is simple to work; burns steadily, producing a powerfu long flame arc, and is comparatively economical in current The mercury vapour lamp is being discarded in favour of it and the use of electrodes other than carbon is said to produc light of a less range of usefulness from the therapeuti point of view. There are no reflectors and no spurting pieces of metal during burning, so that a small circle o patients can sit round in as close proximity as is desired Several of the big London hospitals, and sanatoriums, tuberculosis dispensaries, infirmaries, and children's institution in different parts of the country, have installed this lamp and report that therapeutic results are easy to obtain.

General light bath with "Westminster-Eidinow" lamps.

An Address
ON
CONSCIOUSNESS.

Being the Presidential Address to the Section of Psychiatry, Royal Society of Medicine, delivered on Nov. 11th, 1924,

BY CHARLES S. MYERS, C.B.E., M.D. CAMB., Sc.D., F.R.S.,
DIRECTOR, NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY.

LITTLE more than a generation ago, at one of the largest London hospitals, its most distinguished physician once observed to one of his clerks fresh from undergraduate Cambridge: "The sooner, my dear fellow, you forget your physiology, the better it will be for your medicine." Such advice would hardly be ventured to-day. Nor, I think, would a medical student be now told by any of ourselves: "The sooner you forget your psychology, the better it will be for your psychiatry," not perhaps because psychology has proved now more useful in furnishing an applied science than physiology proved then, but because at present, with rare exceptions, the medical student is afforded no opportunity of learning psychology, but has to pick up a smattering of it as best he can when he comes to approach the problems of psychological medicine.

If for this reason alone, it may be not altogether a disadvantage for the Chair of the Section of Psychiatry of the Royal Society of Medicine to be held from time to time by a psychologist whose excursions into psycho-pathology are few and narrow—in my own case limited to the years of the recent war. I need hardly say how honoured such a one feels with this invitation, and what a responsibility it places on him when he endeavours to present certain views and aspects, derived largely from a study of *pure* psychology, which he hopes may prove interesting and suggestive to those working in the applied field of *medical* psychology.

CONCEPTIONS OF CONSCIOUSNESS.

In this address I propose to review our conceptions of consciousness.

Let us first consider its main forms or modes. These have for two generations past been classified as cognitive, conative, and affective; the cognitive consciousness dealing with the experiences of sensing, perceiving, apprehending, imaging, recollecting, imagining, and other kinds of knowing and thinking; the conative consciousness with the experiences of acting or striving or willing towards a more or less definite end; and the affective consciousness with its experiences of pleasure and displeasure. The inadequacy of this classification has been increasingly, if but tacitly, felt. Thus, the affective consciousness deals with far more than affective tone—mere pleasure and displeasure. (Indeed, as I shall presently indicate, I hesitate to regard them as primitive.) It covers every kind of feeling, not merely emotional, but also intellectual—feelings of familiarity, certainty, doubt, relationship, and so forth. It covers feelings relating to the *acts* of the self, as well as to the *condition* of the self.

Moreover, when we are engaged in apprehending or recollecting any situation, it is obvious that we must inevitably employ the conative, as well as the cognitive, mode of consciousness as above distinguished. Indeed, knowing becomes a form of doing. Hence, attempts have been made to classify the modes of consciousness not on these older lines, but on the basis of a distinction between doing and what is done, between process and product—i.e., between act and content—e.g., between the act of perceiving and what is perceived, the act of remembering and what is remembered, the act of deliberating or deciding, and what is decided on or deliberated about. According to this scheme, consciousness is classifiable along the lines of self-activity and the outcome of self-activity. But even this appears unsatisfactory, because, in the first place, it leaves the affective consciousness out of consideration and, in the second place, it implies that whatever product of consciousness appears to be "presented" to the self is really a product of self-activity.

Two Classes of Feelings.

In relation to the self and the self's activity feelings appear to me divisible into two classes—the "ipsi-affective," attached to the self, and the "actu-affective," attached to the self's acts. Thus, in the state of *strain* or enhanced vitality produced by a favourable environment, the ipsi-affect is a feeling of "exhilaration" (evolving into "gladness"), the actu-affect is one of "interest." In the state of strain produced, on the other hand, by an unfavourable environment, the ipsi-affect is a feeling of "uneasiness" (evolving into "distress"), the actu-affect is one of "repugnance." Again, in the state of *rest* produced by a favourable environment, the ipsi-affect is a feeling of "ease" (evolving into "bliss"), the actu-affect is one of "contentment"; while, in the state of rest or reduced vitality produced by an unfavourable environment, the ipsi-affect is a feeling of "depression" (evolving into "sadness"), the actu-affect is one of "apathy."

In the second place, is it reasonable to suppose that when we suddenly hail a friend or are struck with an idea, the corresponding percept or thought is *consequent on* an act of the self? Is it not more in accordance with common sense to suppose that such a percept or thought is a "presentation" to the self, rather than that it is produced by the self? Are there not occurring a number of acts that yield conscious products—acts which are independent of the self? Are not the acts of sensing and the spontaneous revival of past experiences examples of these, and are not their mental products—sensations, say of blue or noise, and memories, say of a forgotten duty—*received* by instead of being *created* by the self? To this it may be replied that such acts and products are at first mental but not conscious, and that the only consciousness which is possible for us is the self's consciousness—the consciousness arising from the activity of that highest unitary system which we call the "ego." Blue is not a sensation until the self attends to it. Before it so attends, something is presented—some mental content produced by the mental act of sensing, which involves not self-activity, but the activity of some lower mental function—mental but not conscious.

The attempt may be made to evade this difficulty by supposing that originally—e.g., on the first occasion that the sensation was ever experienced, the self was consciously engaged in the act of producing it, but that in later life the act had become so habitual that, self-activity becoming no longer involved, the act had been relegated to lower nervous levels.

The Nervous Paths.

To this it may be rejoined that there is no decisive evidence that, as with practice an acquired act becomes a habit, the nervous paths are essentially different (save in so far as concomitant redundant acts are abandoned) from those which were employed during the acquisition of that habit. It may well be that the presence or absence of the consciousness of self-activity is dependent on the degree of resistance which the nervous processes encounter, and that practice wears down this resistance, canalising or facilitating one and the same path as the unpractised conscious act gradually becomes a habitual one. But if consciousness is dependent on the extent of such highest resistance, we have to remember, on the other hand, that when that resistance is excessive—owing to the harmful effect of the experience on the organism—consciousness is again abolished. True, the resistance or inhibition against entry into consciousness may appear to be here of another kind—due to incompatibility instead of to novelty. But elsewhere in mental life we have at least two other seeming examples of an intermediate range, on either side of which the appearance of one and the same function is favoured.

Thus, for the avoidance of suggestion, the field of consciousness must not be too diffuse, nor must it, on the other hand, be too restricted. The condition of hypnotic suggestion, as is well known, is induced by fixation of attention within narrow limits—gazing at a point of light, thinking concentratedly of going to sleep, &c. But the suggestibility of a person is also increased in the opposite condition of reverie, brought about by asking the subject to relax his attention and to "think of nothing." Somehow each of these antagonistic states leads apparently to the same result—the abolition of self-control, and the acceptance of ideas which under normal conditions would be rejected.

Emotional Experiences.

The second example which I have in mind relates to the development of emotional experience. There is good reason to suppose that one of the principal factors determining our actual experience of an emotion is the degree of resistance which prevents its expression in bodily activity. If that resistance be not great, if, say, a dangerous situation is fairly readily soluble by the reaction of flight, the emotion, of fear, may not be felt. But when great resistance or conflict is offered to such expression, the emotion is at once developed. A similar standpoint has been taken by some, e.g., Prideaux, who have carried out observations on the psycho-galvanic reaction. Within certain limits this reaction is more intense when the emotion with which it is associated is less felt. To take the extreme case of the idiot, he gives more free expression to an emotional situation and develops the psycho-galvanic response to it more strongly than a person of normal intelligence, but there is good reason to suppose that he *feels* the emotion less intensely. A certain resistance or conflict in regard to expression—what Drever calls a condition of "feeling tension"—seems essential before emotion can occur.[1] But Drever believes that emotional feeling is favoured not only "when there is some check, or at least pause, in the attainment of the end or satisfaction of the impulse," but also "when the end" so far from being checked, "is attained so quickly or abundantly that action cannot keep pace with feeling."

DEVELOPMENT OF CONSCIOUSNESS.

We may well wonder how excess or defect of a given condition may lead to the same result, but an explanation in evolutionary terms appears worthy of consideration. Along these lines we may conjecture that it is pre-eminently from the *moderate* condition that new effects are developed, the more primitive effects persisting in *extreme* conditions that fall far short, or are far in excess, of the moderate. On this supposition, extreme suggestibility is a primitive mental characteristic, which has gradually become reduced in the course of evolution under conditions of moderately restricted attention. By the same reasoning, readiness to experience emotion is a characteristic of the *primitive* mind. In the higher organism it persists when its end is extravagantly attained or when there is considerable check in the attainment of its end; on the other hand, it becomes reduced or abolished when that end is attained without undue speed and fullness, on the one hand, and without much check or conflict on the other.

So also in regard to consciousness and resistance. The primitive condition of the living organism is such that its mental activity is largely unconscious. Conscious activity has been differentiated from it. From this it must not be inferred that the beginning of conscious life is to be sought in reflex action; the reflex act is rather the decadent relic of a primordial mental activity which preceded the development of conscious activity. Mental activity is prior to habitual and reflex action; the mechanical is an abstraction from the truly mental.

The distinction we have drawn between act and content, between process and product, is characteristic of all vital activity. We can separate the act or the process of secreting from the secretion or the product of that process. Whether the level of the nervous system be high or low, whether or not there be attendant consciousness of the act or of the content, we can speak of the process on the one hand, and of the product on the other, and we may suppose that every such act involves mechanical work and hence the expenditure of force, and that with every act energy is expended, involving a degradation manifest in the form of electricity, heat, &c. But vital activity is characterised by anabolic as well as by katabolic processes—by creative as well as by destructive changes. Furthermore, these creative changes are characterised by some degree of purposiveness; they do not occur merely by blind chance. Biologists are coming generally to recognise the insufficiency of purely accidental variations as an explanation of the origin of species. Hence in addition to the explosive force of mere acts, we have to consider the more continuous setting or direction in which those acts take place. It is the complexity and prominence of this directive setting that pre-eminently distinguishes the nervous from all other tissues of the living organism, and that above all distinguishes the conscious from the unconscious mental life of that organism. And as direction depends on pre-existing dirigibility, direction itself demands plasticity, in contrast to fixity, of reaction.

Environmental Stimuli.

It is fairly obvious that if only one response to a given stimulus were possible, consciousness would be of little value and would hardly have arisen. Its utility arises when alternative reactions are possible, when some sort of choice has to be made between them, for the benefit of the organism as a whole, or when, as in an important emotional situation, it is essential that no other conflicting reaction be made to another simultaneous experience. Consciousness is thus a selector of alternative *responses*.

It is also a selector of alternative *stimuli*. If, owing to uniformity of external conditions or to the immobility of the organism, the organism were unable to alter its relation to the environment, consciousness again would hardly have arisen. One of its most important functions is to maintain an environment that is favourable and to avoid one that is unfavourable, whether that environment be a physical one, say in the form of external nourishment or temperature, or a mental one, say in the form of appropriate or noxious thoughts.

But in order to act effectively as the selector of alternative reactions and of its environment, relatively small variations in the environment must differ in the reactions evoked. If two slightly different stimuli gave identically the same response, no purpose would be served by our being conscious of any difference between them.

These, then, are the main functions and conditions of consciousness; and in realising them we realise still more clearly how all consciousness must form part of "self-consciousness," by which I mean not necessarily the knowledge, the awareness of the self, but the involvement of that highest integration of activities which is known as the self within the indivisible, organic, individual organism. Consciousness thus functions as the coördinator of all the past and present experiences of the organisms so as to give direction to the selection of its future activities and environment, in compliance with the organism's sanctions and ends.

The Complexity of Primitive Experiences.

I spoke just now of the reflex act as a decadent form of mental activity. It has been too common an error to regard the simple in life as prior to the complex. We are apt to forget that the most lowly unicellular organism eats, breathes, secretes, excretes, reproduces, and exhibits irritability, contractility, and even apparent choice and ability to learn by experience, whereas in the higher organism such functions are specialised in its different tissues. The vague complex, in other words, precedes the differentiated simple. So it is largely in the life of consciousness. Simple sensations are not the first experiences. The first post-natal or even pre-natal experiences are vague affections of the self, or of what will come in time to constitute the self, as later it becomes differentiated from external situations, and as later external objects come in turn to be differentiated from external situations. At quite an early period many of the infants' experiences, especially the visual, become projected first as situations, then as objects, instead of being as at first little more than affections, so to speak, of the self. It is only gradually that the separate, simple sensations, say of whiteness, softness, and sweetness, are differentiated from these objects. But these sensations, we must remember, are not wholly projected. Red, for example, clearly resides in the object, but pain lies in ourselves, while such sensations as those of temperature and taste occupy a half-way position.

---

[1] Instinct in Man, second edition, 1921, p. 272.

The observations of Head and Gordon Holmes in conditions of thalamo-cortical interference indicate that such projection may be lost in lesions of such sort. A prick may be no longer projected as such, but described by the self as a characteristic change in, as an affection of, itself. Indeed, under normal conditions the less projected the sensation, the more it approximates to an affective modification of the self. Titchener is doubtless right in believing that sensations (hence cognitive states in general) have become evolved out of feelings. I believe that this power of projection, the ability of the self to regard its own change of states as something outside itself, is of far greater importance than is generally supposed. It surely culminates in the self looking down not merely on external independent objects, but also on its own *other* selves who come to be regarded as acting under its jurisdiction. Thus the most consummate actor is said to be he who, though he feels the emotions he portrays, experiences them in such a way that it is as if he were looking down upon another self that actually feels them. Something of the same effect, though doubtless of different causation, is observable in that transient, slightly pathological condition known as "depersonalisation," common to large numbers of us, wherein the external environment appears for the moment as strange, and we seem to be looking on another instead of on ourself as really experiencing it and acting on it. It occurs still more strikingly, of course, in the more definitely morbid condition of loss of reality. Similar processes may account for that alternation of personalities behind which there is a continuous personality that knows the acts and experiences of the others. The well-known limits of post-hypnotic suggestibility indicate the same preservation of a higher, dominant, however dormant self. The integrity, the intactness of this supreme self may prove, I even suggest, to be the future criterion between so-called psycho-neurotic and psychotic conditions.

THE BUILDING UP OF CONSCIOUSNESS.

While the simple is, so to speak, distilled from the wider complex, nevertheless synthesis goes on, as well as analysis; and many instances will easily occur to one where new experiences are dependent on an integration of stimuli or of more primitive experiences. On the one hand, where a reflex is inherited or a habit is acquired, consciousness is useless, since the stimulus inevitably releases one and only one reaction. On the other hand, where an instinct appears, consciousness (let us call it instinct feeling) is essential, because intelligence can be brought to bear so as to improve by growing experience the imperfect instinctive reaction to the situation. Where emotion enters, the number of alternative conflicting instinctive reactions to a stimulus has become manifold—e.g., in the case of fear, flight, rigidity, flaccid palsy, crying, clinging to the parent, fighting at bay; and their respective *instinctive* feelings become integrated about a common object on this higher plane to create *emotional* feeling. Where sentiment enters, a number of alternative conflicting emotional feelings have become integrated about a common idea, and a new *sentiment*-feeling—e.g., that of love or hate—emerges.

The importance of the integration of such alternative conflicting mental states as the creator of new ones can hardly be over-estimated. Rivers has from the ethnological standpoint attributed new cultures to the clash of immigrant with indigenous ones; and it seems possible that the creations of the inspired genius may be the unconscious product of similar conflict.

OUR KNOWLEDGE OF LIVING SUBSTANCE.

Let us now consider what we know of the activity of living substance. It exists in two forms: (1) intensive and momentary, and (2) moderate and prolonged. The contractions of striated muscle illustrate intensive and momentary vital activity; the reactions of heat and cold spots offer another example. There appears to occur a firing off of already prepared, explosive material, followed fairly rapidly by fatigue. The contractions of unstriated muscle illustrate the more moderate and prolonged form of activity, where tone and long-continued adaptation seem to replace the explosive force and consequent fatigue characteristic of the first-mentioned form. Again, the tone and the posture in striated muscle, both of them moderate, long-continued, and relatively indefatigable, illustrate the same form of activity. They involve a directive balance, a delicate nervous coördination between two opposing muscles, flexor and extensor. The sensations of warmth and coolness depend on a similar mechanism. In contrast to the *spot* system subserving heat and cold, this *diffuse* spot-less sensibility involves a close coördination between the mechanisms for warmth and coolness, as is exemplified first in the set state of balance that occurs in the form of "sensory adaptation," a kind of stationary posture, as it seems to me, between the opposing mechanisms of warmth and coolness, when the skin is exposed for some time to a warm or a cool environment, and secondly, in the action resulting from disturbance of that balance that occurs in the form "sensory contrast," when that environment is suddenly replaced, say by a neutral one. Such phenomena as adaptation and contrast do not occur in the spot system; there we have merely sudden, ungraded reaction and fatigue.

Thus we come to contrast powerful energetic explosive acts, followed by a loss of material available for the allowance of further acts, on the one hand, and the more moderate, more graded activities on the other hand, involving reciprocal inhibition and facilitation, and finally yielding a long-continued set or state of adaptation or attitude.

Acts and Attitude of Mental Activity.

May we not usefully distinguish these two forms throughout mental activity, even up to the highest conscious processes? In other words, have we not, on the one hand, the momentary, relatively fatigable acts of apprehension, recall, decision—of *expression* in general, and on the other the long-continued, relatively persistent sets or attitudes—mental *postures*, if you like, in which those varying acts take place? On the one side, we have the more mechanical acts; on the other, the more directive attitudes—though, of course, the acts themselves are far from being devoid of a certain coördination and direction. We recognise thus in mental activity a more mechanical factor and a more directive factor, each involving the expenditure of work; but whereas we have some conceivable idea of the nature of the former, we have none whatever of the nature of the latter.

We might well pause, did time permit, to consider what is the effect of profound morbid changes in attitude on the consciousness of acts. Two obvious and opposite directions of change at once present themselves. At the one extreme, attitude is unusually persistent and unvaried. According to the old diction, Semper idem sentire ac non sentire idem est. At the other, attitude is to all intents and purposes non-existent; the mental acts follow one another over a vast field whose meaning is changing with bewildering speed. So far as consciousness is concerned, have we not here yet another of the illustrations already given in this paper that "extremes meet"?

All that we can say of any higher mental attitude is that it is closely associated with interest—innate (i.e., immediate) or acquired (i.e., indirect). Hence has arisen the wider notion, extended not only to our higher attitudes but also to our higher acts, that they are dependent on affects, whether the affects partake of those moderate, more continuous forms or attitudes known as interests and moods, or of the more powerful, less lasting forms or acts known as feelings of emotion and of sentiment. Hence, too, has arisen the notion that there is a common fund of mental energy of affective origin, a single libido which can be drained off now into one, now into another channel of mental and motor activity in such a way that what one channel gains involves a corresponding loss among other channels. We reach, indeed, Spearman's conception of a central factor common in various degrees to all forms of intellectual activity.

Spearman does not attempt to define the nature of this general or central factor. He calls it "*g*," but it must not be identified, as is so frequently done, with our notion of "general intelligence." Whatever it is, it is not this. Spearman admits that he is quite unable to express "*g*" in psychological terms. Its presence and its amount are determined by mathematical principles based on the inter-correlation of the various intellectual activities with one another. He prefers to regard "*g*" as an unknown physiological factor, and he admits Godfrey Thomson's criticism that the very existence of "*g*" is only one of alternative conclusions that may be drawn from the mathematical studies of correlation which he employs to establish and to measure it.

THE AFFECTIVE CONSCIOUSNESS.

The early neglect of the importance of affects has resulted, I think, in an exaggerated swing of the pendulum to the opposite extreme. It is, I think, ridiculous to suppose that the energy informing our acts is derived solely from our affects. We may, however, reasonably consider the view that, using the term in its widest sense, our attitudes serve as keys that unlock the energies resident in our acts. It is also ridiculous to suppose that our acts depend for their energy on *drainage* from one set of channels to another. The modern studies of repression alone suffice to prove that censoring, as the Freudians term it, involves actual work in the imposition of resistance. The mind is not comparable, as according to McDougall, to a vast sewerage system, in which the active channels drain off energy from those which are ipso facto rendered inactive; inhibition involves as much work as excitation.

The same exaggerated importance of the affective consciousness has led to the attribution of all forgetting, every slip of the tongue, to emotional conflict and inhibition. Surely prolonged laboratory experience in learning large numbers of senseless syllables or in rapidly naming long series of familiar objects suffices to show the extravagance of this view. Deterioration or disorder in cognitive processes is not always dependent on affective factors. We must recognise that the act may suffer through its excessive exercise, as well as through direct inhibition by other acts; at the same time fully admitting that the attitude which suffers mainly through flagging interest or conflicting feeling may also thus influence the act.

THE CENTRE OF CONSCIOUSNESS.

That some central factor of general intelligence exists, depending on the functioning of the highest system of mental activities known as the self, there can be little reasonable doubt. But its conception is also commonly bound up with that of localising the various conscious processes, which are *not* those of general intelligence, in different regions of the brain. For generations past it has been customary to believe in special centres for the various motor, sensory, and perceptual activities involved in speech, and to regard them as "seats of consciousness," connected with one another and presumably with that highest central centre of the self or ego. It is interesting to find that the recent researches into aphasia by Head have enabled him to produce cogent evidence against such a view.

For my own part, in my Cambridge lectures, I was long wont to protest against it by means of the following illustration. If I wanted to travel by rail from Cambridge to King's Cross, it would be essential for me to pass through Hitchin. A block at Hitchin would prevent my arrival at King's Cross. But I should not be justified in confusing Hitchin with King's Cross and in transferring the block at Hitchin to King's Cross. So too, if a certain occipital area must necessarily function in order that, say, an apple may be perceived as such, I should not be justified in describing that area as a "visuo-psychic centre" because I fail to apprehend an apple when that area is disorganised. All that I can legitimately infer is that that occipital area is essential for visual perception, just as Hitchin is essential for me to reach King's Cross. Seats of different consciousness must not be thus fallaciously localised in relatively small different areas of the cerebral cortex.

A similar error endangers Head's earlier conjection (in his work with Gordon Holmes) that the thalamus is the "centre of consciousness for certain elements of sensation"[2] which he infers from the results of interference of the normal connexions between the thalamus and the cerebral cortex. No doubt he would himself admit that if we interfere with a small part of the central nervous system it is impossible to suppose that that part remains the seat of conscious processes. Consciousness depends on the self. The activities of the thalamus can only affect consciousness by forming part of those activities which contribute to those of the self. All that we can safely infer is that when the thalamus is separated from the cerebral cortex its activities affect the self in a manner different from that when its normal relations to the cortex are intact. We cannot posit a "centre of consciousness" in any form.

THE NATURE OF CONSCIOUSNESS.

This brings me, in conclusion, to a brief study of the nature of consciousness itself. There was a time when mind was regarded as the product of the brain, just as bile is regarded as the product of the liver. This was succeeded by an age when mind and living matter were considered to be so absolutely different in character that for this, if not for any other reason, it seemed absurd to compare mind with bile as a "secretion" of living substance. Instead grew up on one side, the theory of psycho-physical parallelism—that mental and neural processes are two different aspects or reflections of one and the same unknown activity—and, on the other side, the theory of interactionism; that so far from being parallel they are independent and may each, according to circumstances, influence and control the other.

Times have now changed. Substance proves no longer as "substantial" as it appears. We are no longer content to regard matter as composed of solid atoms. The structure of the atom is now revealed to us as a constellation of ions, each of which appears to be merely a charge of electrical energy, endowed with inertia, mass, weight, and structure.

What exactly is the relation of such a view to the hypothesis of a structureless, continuous, almost perfectly elastic ether is so far uncertain. But the phenomena of light prove no longer to be solely explicable in terms of the undulatory theory; some of them now demand a corpuscular theory for their solution. At all events, matter is now regarded as a manifestation of electric forces, a product of activities.

MIND AND MATTER.

What now of mind? Is not this likewise a product of activities? Is the difference between mind and matter so fundamental as a hundred years ago it appeared? Are not the hidden activities of mind and matter of greater import than their more obvious products? Are not the respectively material and mental characters of these products due ultimately to such activity itself?

---

[2] Brain, 1911–12, xxxiv., 181.

When we come to consider the difference between mind and *living* matter the distinction is reduced almost to vanishing point. For it is essentially the same purposive, directive, plastic, and constructive characteristics, distinguishing living from dead matter, which, raised to a still higher power, distinguish both nervous and mental activity from the activity of other living tissues. The problems of life that confront the physiologist are precisely those of mind that confront the psychologist. Life and mind must ultimately be solved in similar terms. From each we can abstract the mechanical, comparable to what we know of the activities of lifeless matter. But it may well be that the apparently blind mechanism of which physics treats is only an abstraction from a purposeful direction that plays its part in the larger universe regarded as an organism, just as we are bound to conceive of such direction even in the lowest living individuals, even in the lowest physiological levels of the higher living organisms.

With progressive evolution of these various levels have "emerged," according to the recent terminology of Lloyd Morgan and Alexander, the various levels of mental activity. It may be that the term "differentiation" will often be found more useful than that of "emergence," so often is the new really pre-existent, though in a primitive, vague, undifferentiated state, in the old. But admitting also the "creation" of new forms with the progress of evolution, may we not sometimes regard the mechanical forms of activity as being really a degradation of still higher forms? Because electrical energy is the only energy in which that of the nervous system reveals itself to us, can we deny the possibility that this is a degradation of some higher, what I may term "psycho-neural," energy, which assumes a more psychical character in the highest levels of the nervous systems of the most highly organised individuals, whose wider and more plastic areas are more complexly integrated together to function as a single entity?

These are among the problems which seem to be worthy of consideration in the broader study of consciousness.

OBESITY IN CHILDREN,

WITH SPECIAL REFERENCE TO CARBOHYDRATE METABOLISM AND ITS MODIFICATION BY THE ADMINISTRATION OF CERTAIN DUCTLESS GLANDS.

BY F. S. LANGMEAD, M.D. LOND., F.R.C.P. LOND., M.R.C.S.,
PROFESSOR OF MEDICINE, UNIVERSITY OF LONDON; DIRECTOR OF THE MEDICAL CLINICAL UNIT, ST. MARY'S HOSPITAL, W.;

AND

EDWIN G. B. CALVERT, M.D. BELF., M.R.C.P. LOND., D.P.H.,
ASSISTANT TO THE DIRECTOR, MEDICAL CLINICAL UNIT, ST. MARY'S HOSPITAL, W.

CHILDREN are not uncommonly brought under medical supervision and treatment on account of obesity which is of no common order, but gross in its degree and associated with a soft, velvety texture of the skin, gynæcomastia, prominently feminine conformation of the body, and placidity of temperament. These features often lead to a diagnosis of dyspituitarism on quite insufficient grounds, and in many cases the onset of puberty is accompanied by loss of fat and development thereafter on ordinary lines. In other cases, stunting of growth, mental backwardness, and genital hypoplasia provide the classical syndrome of Fröhlich, while in still others there is skeletal overgrowth described by Cushing. Of the last eight cases under our observation, four have been of boys and four of girls. The sexual development of two of the girls, aged 9 and 13 respectively, has not been ascertained, but that of two of the boys, judged by the external sex organs, is obviously rudimentary. The other two boys are well above the usual height for their age, and the same is true of two of the girls. One of these, aged 10, is 4 ft. 7¼ in. high and weighs just under 9 st.; the other, aged 13, is over 5 ft. high and weighs 12 st. 13½ lb. In both menstruation has begun. No malady preceded the obesity, except in the case of the precocious and overgrown girl aged 10, in whom it began after encephalitis lethargica. Cases having a like relationship were referred to by Prof. A. J. Hall in his Lumleian lectures (1923).[1]

Endocrine Glands in Relation to Obesity in Children.

Against accepting cases of obesity of this nature in children too readily as examples of dyspituitarism, it may be argued that obesity alone will provide the gynæcomastia, the "pudding face," and the feminine contours. When, however, the obesity is accompanied by disordered physical or mental growth, whether in the direction of retardation or the reverse, there is more reason for regarding it as other than exogenous and for looking to the endocrine glands for an explanation. It is known that defects of the hypophysis may be found in cases of obesity, whether accompanied by infantilism or by precocious growth, and again, that by ligaturing the stalk of the gland, or dividing it in young animals, hypoplasia of the gonads may be caused. Nevertheless, in clinical medicine it is difficult to assess the part played by other ductless glands in the altered economy. How far, for example, is the hypogenesis of the sex glands responsible for the obesity or for the overgrowth when it occurs? We know that obesity is often a feature of the end of the climacteric, and that eunuchs are apt to be magnificent specimens of humanity in stature and muscular power. Of the rôles played by the thyroid, the pancreas, or the suprarenal glands in this disorder we are ignorant, and, despite much valuable work, uncertain of the precise functions of the several parts of the hypophysis itself. A tumour of the anterior lobe cannot fail to compress the posterior, whilst an experimental lesion cannot be performed on one lobe without affecting the other. A discussion on the inter-relations between the different parts of the gland and between the whole gland and other ductless glands, takes us into the region of hypothesis, where much is proposed and little substantiated.

Obesity of the kind under consideration may be due to a pituitary tumour, which, if it is large enough, provokes its particular signs of pressure, notably bitemporal hemianopia. The diagnosis does not remain in doubt in such cases, but they represent only a very small proportion. In none of the eight cases were these signs present. To inculpate the pituitary gland, two other signs are often sought—changes in the pituitary fossa as seen by Röntgen rays and increased tolerance for carbohydrates. Radiographic evidence is more often lacking than not, and was only forthcoming in two of our cases, the radiograms showing reduction of the size of the fossa in one case and enlargement in the other. The absence of changes in the fossa in the others calls for no comment, for, except in the presence of a tumour or when the functional capacity is below normal from want of full development of the gland during fœtal life, no change in the size of the fossa would be expected.

Carbohydrate Tolerance in Obesity.

In all the cases the usual test for carbohydrate tolerance has been employed, various doses of sugar up to 300 g. having been given by the mouth, and the urine subsequently examined for glucose. No glycosuria resulted even with the large doses, except in one case (Case 3 below). Might not a similar result occur in exogenous obesity alone, for such patients often eat carbohydrates in excess and obviously store them? In any case the validity of the test is rendered somewhat dubious by the pronouncement of MacLean,[2] that no amount of ingested sugar will cause glycosuria in a normal person. Against this, however, it must be stated that when equally *large* amounts of sugar were given to other children, comparable in age or in weight, glycosuria resulted.

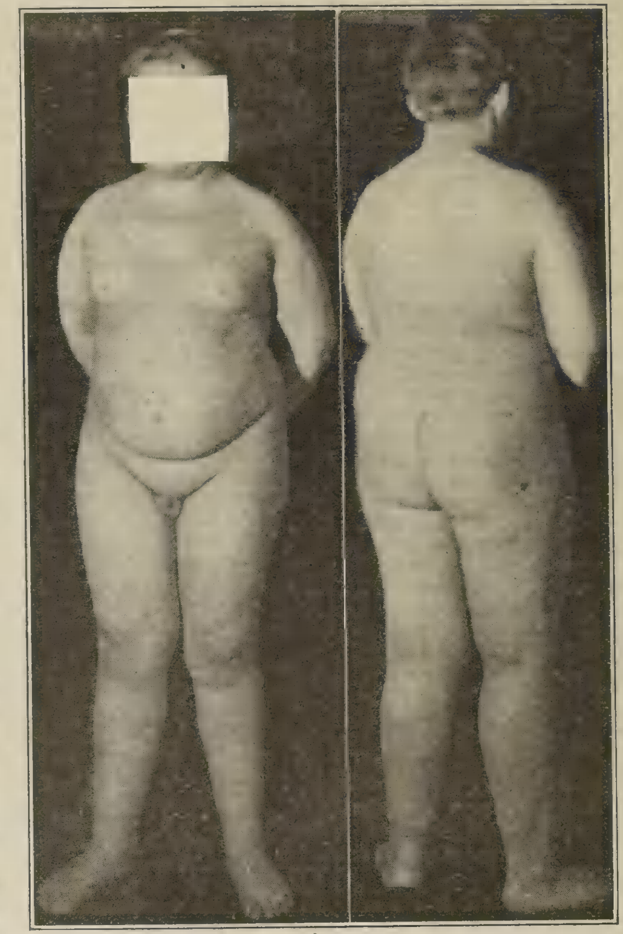
---

[1] Hall, A. J.: THE LANCET, 1923, i., 731.

Modern biochemical methods of examining the blood permit the study of carbohydrate tolerance in greater detail, and several cases such as ours have been investigated in this way. The blood-sugar curves, after ingestion of known amounts of sugar, have not been found to resemble each other closely or provide any characteristic form in cases of reputed dyspituitarism. This examination has been carried out in our cases, doses of from 50 to 220 g. of sugar having been administered and the blood-sugar values estimated at quarter- or half-hourly intervals and plotted out. Our results have agreed with those of others, the curves obtained having variable features, though all deviated from the normal to a greater or less extent.

In view of the various endocrine defects which might explain the combination of obesity with infantilism or with overgrowth and premature development, it occurred to us that useful information might be obtained by determining the manner in which the blood-sugar curves could be modified by the administration of certain ductless glands. Four cases were selected for this purpose, and were those of three boys, aged 10, $11\frac{1}{2}$, and 14 respectively, and of one girl, aged 13. In the two younger boys the obesity was accompanied by genital hypoplasia, but there was no mental backwardness, whilst the eldest boy and the girl were examples of obesity with overgrowth, with normal sex development.

FIG. 1. FIG. 2.



CASE 1.—F. X., aged 10, obesity with genital hypoplasia.

Case Records.

The main features of the cases may thus be briefly summarised :—

CASE 1 (Figs. 1 and 2).—F. X., male, aged 10. He shows the usual features of the pudding-faced type of dyspituitarism, so named by Fearnsides. Weight 11 st. $11\frac{1}{2}$ lb. Mentally not backward, good-natured, talkative. Sexual development: diminutive penis, left testis undescended. Urine normal. No glycosuria after 200 g. sugar. X ray examination: pituitary fossa very small. Always a big boy, getting fatter since 6 years old.

CASE 2 (Figs. 3 and 4).—B. L., male, aged $11\frac{1}{2}$. Characteristic build, &c., of the same form as Case 1. Undeveloped sexually. Systolic blood pressure 104. Weight 12 st. Mentally bright. Scar in the neck marking an operation for a thyroglossal cyst. X ray examination: sella turcica definitely enlarged. No evidence of intracranial pressure.

CASE 3 (Fig. 5).—B. H., male, aged 14. Great obesity but less infantile in manner; feminine in build. Weigh 10 st. 12 lb. Sexual development probably normal Mentally backward. Sugar tolerance, 0·2 per cent. of suga in the urine after 120 g. glucose. X ray examina tion: pituitary fossa normal. Obesity began at 9 year of age.

CASE 4.—M. A. S., female, aged 13. Excessive growth otherwise dyspituitary appearance and manner. Mentall not backward. Weight 12 st. $13\frac{1}{2}$ lb. No glycosuria afte 220 g. glucose. X ray examination: sella turcica normal.

Method of Investigations.

The laboratory par of the work has bee done by one of u (E. G. B. C.), and th investigations carrie out have been a follows :—

1. The blood-suga curves as compared to th normal.

2. The influence on th blood-sugar curves c pituitrin, adrenalin, an adrenalin and insulin.

3. The influence on th curves of thyroid a compared with desiccat posterior pituitary lobe.

4. The relative influenc on the curves of anteri pituitary (desiccated sul stance), posterior pituita (desiccated substance whole gland (desiccate substance) and whol gland + thyroid.

5. The influence o gonadal extracts.

6. The blood-fat value

1. *Blood-suga Curves.*—50 g. glucos were given to Cases and 3, 70 g. to Case and 100 and also 220 to Case 4. All hav abnormal curves; thes have been confirmed b repeated investigatio The results are as fo lows (see also Fig. 6) :-

(*a*) Starting from fastir levels (which were norma the blood-sugar curv required a time conside ably longer than usual t reach their apices—in o case $1\frac{3}{4}$ hours and in tw others $1\frac{1}{2}$ hours; the cur of Case 3 was rather u common, a slight dip occurring between two peaks of equ height (0·145 per cent.) at $\frac{1}{2}$ hour and $1\frac{1}{4}$ hours.

(*b*) In three of the cases the altitude of the curve w less than normal—all rising to about 0·14 per cent. onl The fourth reached a normal height of 0·17–0·18 per cen

(*c*) In none of the cases did the blood-sugar regain t initial level of about 0·1 per cent. within two hours; t values at the two-hour period varied from 0·12 to 0·13 p cent.

The occurrence of varying blood-sugar curv repeats the findings of other investigators.

2. *Influence of Pituitrin, Adrenalin, and Adrenal + Insulin.*—The same quantities of glucose we given as before, and the effect on the curve was test for pituitrin ($\frac{1}{2}$ c.cm. given hypodermically $\frac{1}{4}$ ho previously), for adrenalin (♏iv.) hypodermically, an for adrenalin (♏ii.) + 6 units of insulin. (See Fig. 7 the curves of Case 1 only are shown as they are repr sentative of the others.)

(*a*) In a normal person pituitrin ($\frac{1}{2}$ c.cm.) was shown n to alter the fasting level or apex of the curve, but onl slightly to prolong its fall. The effect of the pituitrin i these cases was different (see curve B). In all four it hastened the rise of the blood-sugar; in two of these an apex of normal height was reached in normal time, in the other two the altitude was increased appreciably. The fall of the curve (or storage), as gauged by the second hour percentage, was not quite so good as with the sugar alone.

---

[2] MacLean, H.: Modern Methods of the Diagnosis and Treatment of Diabetes Mellitus (Constable and Co.), 1924, p. 54.

(*b*) Adrenalin (♏iv.) in each case produced hyperglycæmia to 0·24 per cent. or over, accompanied by glycosuria; the fall of the blood-sugar was also greatly at fault, the second hour levels varying from 0·155 to 0·190 per cent. (curve C).

FIG. 3.

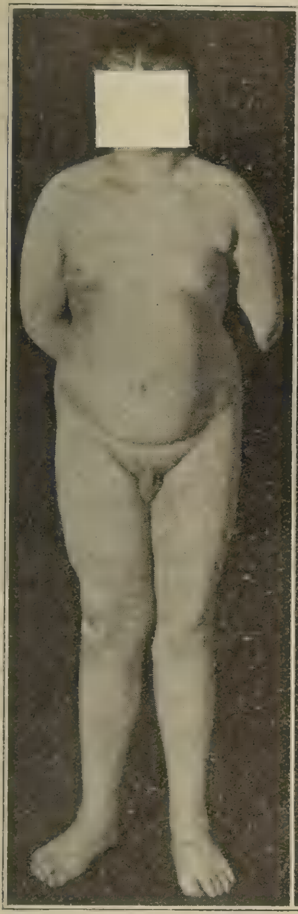


FIG. 4.

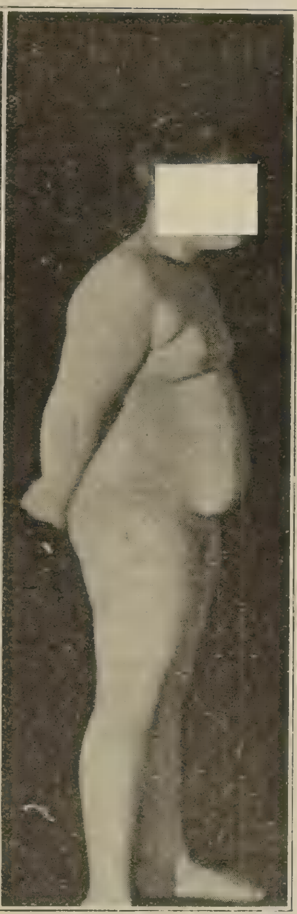
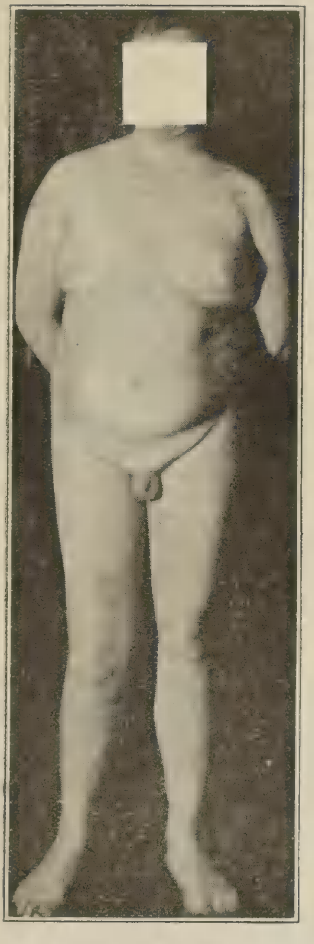


CASE 2.—B. L., aged 11½, obesity with genital hypoplasia.

FIG. 5.



CASE 3.—B. H., aged 14, obesity, normal sexually.

(*c*) Adrenalin (♏ii.) + insulin (6 units) produced in all a blood-sugar curve which was practically normal (curve D).

When no sugar was given, ♏iv. of adrenalin showed a rise to a maximum of 0·128 per cent. only, while ♏ii. gave a maximum of 0·120 per cent. only. It would appear, therefore, that the results obtained can hardly be due to a combination of the separate effects of adrenalin and sugar, but rather that adrenalin had acted merely as a fillip to some part of a sluggish carbohydrate metabolism.

3. *Influence of Thyroid compared with Posterior Lobe* (*desiccated substance*).—Case 1 is shown in Fig. 8 and Case 4 in Fig. 9.

(*a*) 2 gr. of thyroid extract (fresh gland) were given three times daily for nine days previously. This raised the fasting level of the blood-sugar to about 0·126 per cent. in two of the cases, while in the other two the level stood at 0·11 per cent. The rise of the curve was more rapid in three, but the slow fall was enhanced in all four cases (see B, Fig. 8). The effects are, therefore, similar to those in normal persons as regards the fasting level and the fall of the curve.

(*b*) Posterior pituitary, desiccated substance, gr. ii., thrice daily for 27 days, led to a blood-sugar curve practically normal in Cases 1 (see C in Fig. 8) and 2. It is interesting that these cases appeared also to be benefited clinically by the posterior pituitary substance, that both show changes in the sella turcica by X rays, and are infantile sexually. In Cases 3 and 4 (see C in Fig. 9) the fall in the blood-sugar value was made slower instead of more normal, and no benefit derived clinically, though in Case 4 the rise in the blood-sugar was accelerated.

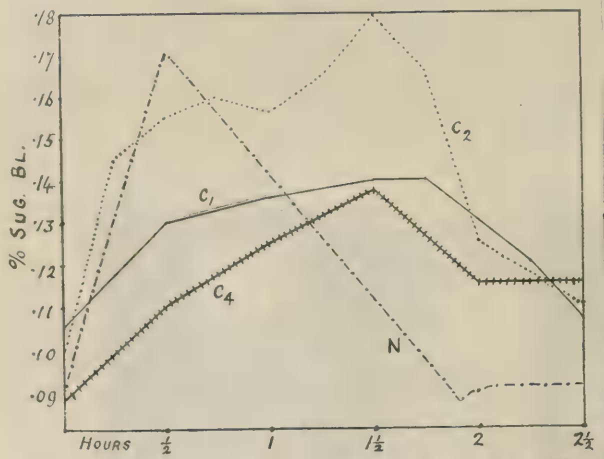
4. *Relative Influence on Blood-sugar Curves of Anterior Pituitary Desiccated Substance, Posterior Pituitary Desiccated Substance, Whole Gland, and Whole Gland + Thyroid.*

(*a*) Anterior pituitary, desiccated substance, gr. 7½, was given thrice daily for four weeks to each. In the two boys (Cases 1 and 2), who were benefited by posterior pituitary substance and whose blood-sugar curves were made normal by it, the effect of anterior pituitary substance was distinctly less beneficial (compare A and B in Case 1, Fig. 10). The blood-sugar curve of the other boy (Case 3) was made normal by the anterior pituitary substance, though the posterior pituitary had had little effect (see A and B in Fig. 11). In the case of the girl (Case 4) both extracts had the same action on the curve, the rise being improved and the fall made worse.

(*b*) Whole gland, 6 gr., thrice daily was also given for four weeks. It provided a blood-sugar curve which showed that its effect was between that produced by anterior and posterior lobe substances in the three cases (1, 2, and 3) in which one or other of these had led to a normal curve (Figs. 10 and 11). In the case of the girl (Case 4), where each separately had hastened the rise and delayed the fall, the whole gland produced a curve representing a summation of these actions.

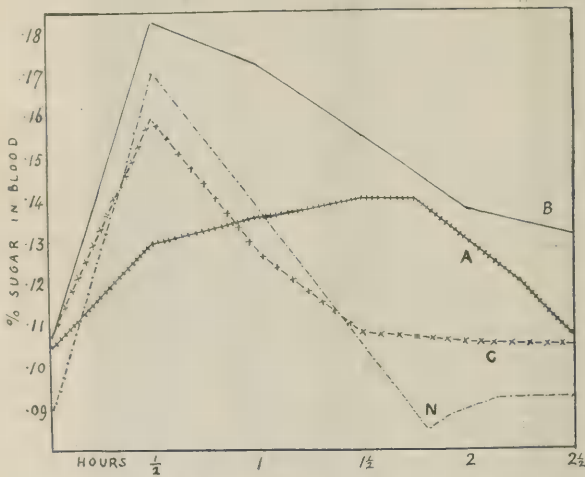
BLOOD-SUGAR CURVES.

FIG. 6.



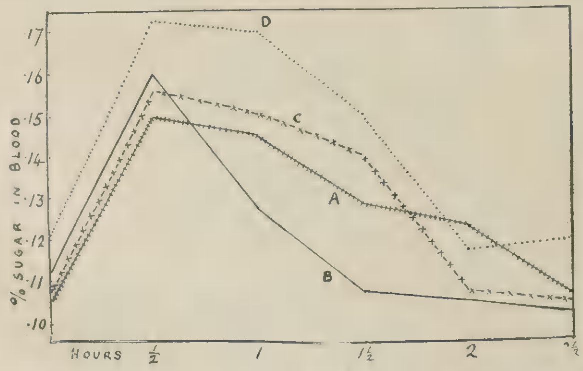
N = normal curve when 50–100 g. glucose are taken. C_1 = Case 1: 50 g. glucose taken; N.S.U. (= no sugar in urine.) C_2 = Case 2: 70 g. glucose taken; N.S.U. C_4 = Case 4: 100 g. glucose taken; N.S.U. [220 g. glucose gave practically the same curve, N.S.U.] The curve of Case 3 is not given to avoid crowding the chart.

FIG. 8.



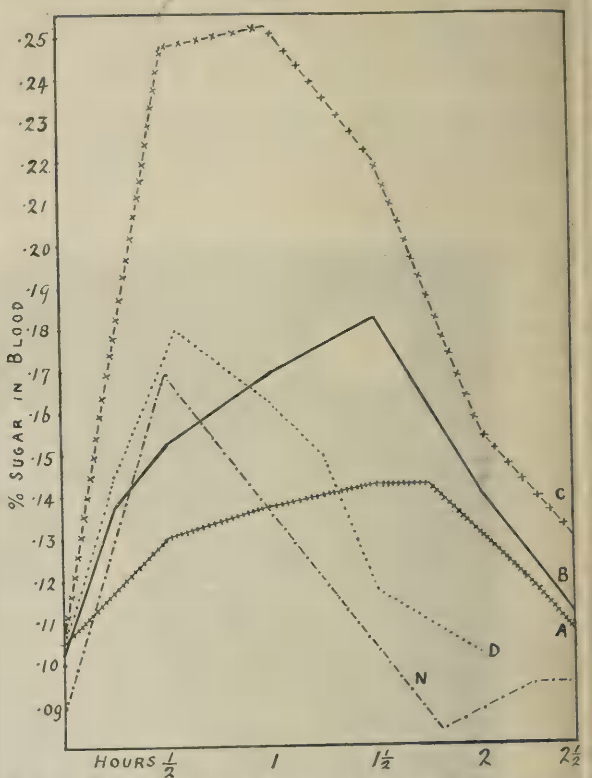
CASE 1.—A = 50 g. glucose. B = 50 g. glucose, thyroid, gr. ii., given t.i.d. for 9 days previously. C = 50 g. glucose; post-pituitary (desiccated substance), gr. ii., t.i.d. for 27 days previously. N = a normal curve. (N.S.U. in A, B, or C.)

FIG. 10.



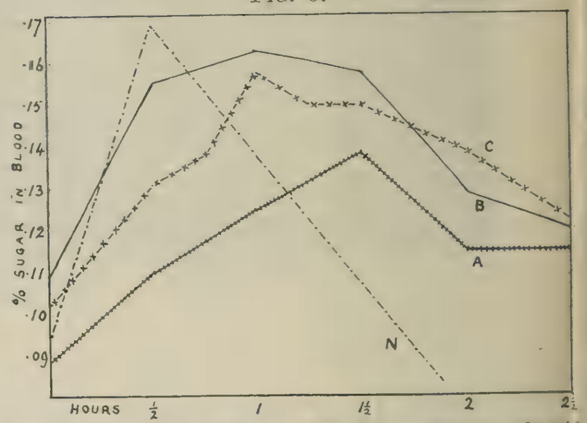
CASE 1.—A = 50 g. glucose; anterior pituitary, desiccated substance (P., D., and Co.), gr. viiss., t.i.d. for 4 weeks previously. B = 50 g. glucose; post-pituitary (desiccated substance, Carnrick), gr. ii., t.i.d. for 27 days previously. C = 50 g. glucose; whole-gland pituitary (desiccated substance, B. W., and Co.), gr. vi., t.i.d. for 4 weeks previously. D = 50 g. glucose; whole-gland pituitary, gr. iv., + thyroid, gr. ½, t.i.d. for 4 weeks previously. (N.S.U. in A, B, C, or D.)

FIG. 7.



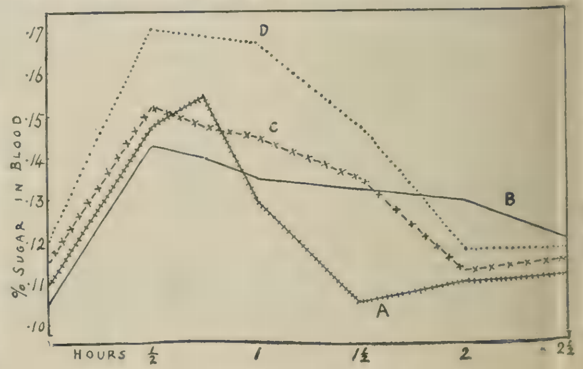
CASE 1.—A = 50 g. glucose (see C_1, Fig. 6). B = 50 g. glucose + ½ c.cm. pituitrin ¼ hour previously. C = 50 g. glucose + ♏iv. adrenalin. D = 50 g. glucose + ♏ii. adrenalin + 6 units insulin. N = a normal curve to 50 g. glucose. (0·6 per cent. sugar in urine in C; none in A, B, D.)

FIG. 9.



CASE 4.—A = 100 g. glucose. B = 100 g. glucose; thyroid, gr. ii., given t.i.d. for 9 days previously. C = 100 g. glucose; post-pituitary (desiccated substance), gr. ii., t.i.d. for 27 days previously.

FIG. 11.



CASE 3.—Description of figure as Fig. 10.

(c) When gr. ½ of thyroid was added to the whole gland the curves (D in Figs. 10 and 11) were found to be at a slightly higher level than when whole gland was given alone in the case of the patients whose blood-sugar curves were made more normal by pituitary. In the other case, where pituitary had caused no improvement in the fall of the curve, this small dose of thyroid seemed to show a beneficial effect.

5. *Gonadal extracts*, using for testicular extract: "Didymin" gr. v., and for ovarian: "Ovarium" gr. v., had no effect.

6. Two of the children (Cases 1 and 4) have been taking a so-called "protein" diet (as fat-free as possible) for four weeks. The possible influence of the amount of blood-fat on carbohydrate metabolism was imperfectly appreciated before the dieting was begun, and unfortunately no blood-fat value estimated. After the dieting the blood-fat in each was within normal limits (about 0·60 per cent. whole-blood total fat), and the blood-sugar curves showed practically normal ascents and apices, but the fall of the curves, though improved, was not yet normal. The dieting was accompanied by loss of weight in both cases, slight in one and as much as 1 st. 5 lb. 2 oz. in the other. Another patient (Case 2), who had continued with his usual diet, gave a blood-fat value of 0·67 per cent. The blood in each case was taken 13 hours after the last meal.

Experiments with Gonadal Extracts.

A preliminary note may be made here of work that is being done in connexion with the sexual infantilism of some of these cases. Bearing in mind the facts: (1) that in the type of obesity just described defect of the genitals is often an outstanding feature; (2) that the administration of the usual gonadal extracts is practically of no value; (3) that Banting has succeeded in the case of the pancreas in separating the internal and external secretions, it was thought worth while to apply the alcohol-fractional-precipitation method, devised by the Toronto School for the preparation of insulin, to the testes of animals in an attempt to isolate their internal secretion for therapeutic purposes.

12 lb. of bulls' testes were extracted with 5 litres of 95 per cent. alcohol, and 5 litres of the filtrate were made up to 8 litres with 95 per cent. alcohol. Further filtration gives a perfectly clear yellow solution. The alcohol was distilled off in vacuo until the residue reached about 200 c.cm. volume. The fat was removed by ether in a separating funnel, and the clear aqueous solution made up to 80 per cent. alcohol by the addition of absolute alcohol. After 24 hours a yellowish syrupy deposit separated out, and the decanted fluid, now free from protein and perfectly clear, had sufficient absolute alcohol added to it to make the alcohol content up to 93 per cent. A marked milky turbidity resulted as in the case of the preparation of insulin from pancreas. In the course of 24–36 hours a considerable granular deposit was obtained by decanting off a colourless, supernatant fluid. This deposit was collected and washed with absolute alcohol and ether in the centrifuge, and finally dried and preserved in a desiccator.

The amount obtained weighed 2·5 g. The substance is readily soluble in water, forming a light yellowish solution. Subcutaneous and intravenous injections were given to rabbits. Even large doses failed to produce any lowering of the blood-sugar level, this proving that the substance does not contain anything of the nature of insulin. No metabolic disturbance was noticed. In the human similar results were obtained.

Owing to obvious difficulties in investigating the effect on metabolism of a product of this sort—especially if it be considered to represent the internal secretion of the testes—it was decided to test the limited stock of the preparation on one of the above patients over a prolonged period. For this purpose the boy B. L. (Case 2) was admitted to the Unit wards on Dec. 10th, 1923. The dose to be given could not be other than empirical. From admission until the beginning of August, 1924, he received daily ½ c.cm. doses of the extract, equivalent to 10 mg. of the dried deposit. It is too early to remark on any changes in sexual development. Mention will be made only of the effect on weight.

From Dec. 10th, 1923, to Jan. 21st, 1924, there was a steady reduction from 12 st. to 10 st. 6 lb. 12 oz., the patient meanwhile taking a full mixed diet. At the latter date the administration of 6 gr. whole pituitary gland (desiccated substance) thrice daily was begun in order to ascertain whether the loss in weight would be accelerated thereby. Judging from the rate of continued reduction in weight—his weight on March 13th, 1924, was 9 st. 8 lb. 10 oz.—one can only conclude that the added effect has, at most, been slight. The pituitary extract has shown, however, a beneficial effect on carbohydrate metabolism, as noted by the correction of the slight delay in fall of the blood-sugar curve that existed. The patient's general health has been well maintained. His weight has fallen steadily and his appearance has become more normal. The other two boys (F. X., Case 1, and B. H., Case 3) have been used as controls, both receiving full diet but no medicinal treatment. Each has gained about 7 lb. in weight during the same period.

Summary.

1. We have found, as others have found before, that the blood-sugar curves in cases of great obesity in children—too readily called hypopituitarism—are diverse in their outlines.

2. In the two cases in which the diagnosis of hypopituitarism is most substantiated (Cases 1 and 2) posterior pituitary substance led to a normal curve; this favours the view that in cases of hypopituitarism it is the posterior lobe which is chiefly concerned with the altered carbohydrate metabolism. Its extract pituitrin, however, had less influence.

3. In a third case (Case 3), with more normal general development and with normal sexual development, the anterior lobe was that which had the correcting effect.

4. The slightly inferior influence on the blood-sugar curve of the whole gland substance in the above three cases appears to indicate that in these cases the good effect on carbohydrate metabolism obtainable by giving the appropriate gland substance may be counteracted to some extent by combining it with the extract of the other lobe.

5. Incidentally, these experiments appear to show that pituitary gland substance given by the mouth is not inert. As far as carbohydrate metabolism goes, the blood-sugar curve being used as an index, it seems logical to administer that lobe of the pituitary which produces the better effect on sugar tolerance. However, considering the cases generally, it will be noticed that the whole gland gives quite good results. In one case the addition of a small dose of thyroid improved matters. The results of the experiments, taken collectively, might be construed as indicating that a properly balanced pluriglandular therapy is required for cases such as these; the suggestion has a pharmacological rather than a physiological basis.

6. Thyroid extract may reduce weight in cases of this kind, but it can hardly be considered an ideal remedy per se, in that it does not restore carbohydrate metabolism to normal.

7. Possibly the production of a normal blood-sugar curve may prove a useful guide to treatment, since when this happened with pituitary substance the patient's condition improved generally.

8. Possibly, too, a somewhat restricted diet, in which the protein is relatively increased, the carbohydrate curtailed, and the fat practically eliminated, may constitute one of the most effective means of stimulating metabolism and reducing weight.

9. The method of preparation from the testes of animals of what may possibly be their internal secretion is described, and also the very considerable loss in weight associated with its administration in one of the above cases.

These investigations are incomplete, and the suggestions put forward concerning the results obtained must only be regarded as tentative.

SPLENECTOMY IN EGYPTIAN SPLENOMEGALY.

SEVENTY CASES.

By R. B. COLEMAN, M.B., Ch.B. Birm.,
AND
J. E. BATEMAN, M.B., Ch.M., B.Sc. Syd.,
C.M.S. HOSPITAL, OLD CAIRO.

Very full and clear descriptions of Egyptian splenomegaly and its treatment by splenectomy have been published by various members of the staff of the Government hospital at Cairo, to whom we wish to express our indebtedness for putting the operative treatment of this disease on a satisfactory basis.[1][2][3][4] Mayo[5] and Moynihan[6] have interesting papers on this subject.

Distribution and Incidence.

Our patients at Old Cairo, to the number of 20,000 yearly, come from all parts of Egypt, and we have also three continuous clinics in the western Delta, and have held three-monthly clinics in the central and eastern Delta, and also immediately south of Cairo. As far as our experience goes we are of opinion that splenomegaly is most common on the eastern side of the Delta and diminishes as we pass to the western side, and further diminishes as we pass from Cairo southwards through Upper Egypt. The great majority of our operation cases come from two well-defined areas, one near Zagazig and the other near Dekernes, both in the eastern Delta. It is difficult to decide whether this is mainly due to recommendations of old patients, or indicates a specially high incidence of the disease in these centres.

Age of Incidence.—This is mainly in the second and third decades. The average age of our operation cases is 19 years, and the limits are 8 and 40 years. We have not found any indication of seasonal variations, as has been suggested by Richards.[3] We see many cases of ascites (of which a considerable proportion are terminal stages in Egyptian splenomegaly) between the ages of 20 and 30 years. In other words, most patients suffering from splenomegaly develop extreme cirrhosis of the liver within a few years. Of our 70 operation cases 13 only were female. We are of opinion that this disparity is not entirely to be accounted for by the greater readiness of men than of women to seek medical aid, but is an indication of a real difference in sex incidence. It is interesting to remember in this connexion that bilharziasis is much more common in the male than in the female in Egypt, and possibly there may be some causal relation between bilharziasis and splenomegaly, as Dr. J. B. Christopherson has suggested, though it has not been possible to prove bilharzial infection in all our operation cases.

The Blood.

In most cases the blood picture was examined after the treatment of concurrent ankylostomiasis and bilharziasis, though occasionally splenectomy was performed after only 15 gr. of sodium antimony tartrate had been given intravenously. Our typical red cell count is 4,000,000 and the colour index 65, while the leucocyte count is between 3000 and 4000. The differential white cell count is about normal. Any considerable degree of leucocytosis has been regarded as a contra-indication to operation, yet we believe there is often a moderate leucocytosis early in the disease, and in view of this we have removed spleens from ten patients whose white cell counts varied from 7000 to 10,000 with results as good as in the cases with a leucopenia. During the four years covered by this report we found a leucocytosis in 32 other cases of splenomegaly with an average count of 13,600, the range of counts being between 10,000 and 24,000. Only two cases of leukæmia were discovered with counts of 4,408,000 reds and 520,000 whites, and 3,116,000 reds and 306,800 whites respectively.

Summary of Cases.

Since the year 1920 splenectomy has been advised in all suitable cases. Of those seen in our out-patients' department quite a number, probably 50 per cent., are refused for operation at once owing to definite contra-indications—e.g., considerable ascites, pellagra, disease of the heart, and advanced general debility. The remainder are advised admission for observation and further examination, and the majority agree to this. Most are suffering from ankylostomiasis and bilharziasis, either rectal or urinary, and these diseases are treated before the blood is examined. Less than half of these thus admitted come to operation—frequently there is some leucocytosis, or some other contra-indication is discovered, and a certain number grow impatient at what they consider the long unnecessary preliminary treatment (two or three weeks or more) and go home. Altogether we have done 70 cases—11 in 1920, 29 in 1921, 13 in 1922, and 17 in 1923.

Operation.

An injection of pneumococcal vaccine is given in every case the night before operation. In the average case we do not now consider the operation a difficult one, and have twice done three cases in a morning's list. We have little to add to the other descriptions of the operation for removal of enlarged spleen. Our incision is through the left rectus, and wherever possible the spleen is delivered through the wound before ligature of the pedicle. Sometimes this is almost impossible owing to adhesions or width of pedicle. At first we found several cases (not included in this number) where we did not deem it wise to remove the spleen owing to the strength of its adhesions to the vault of the diaphragm, but latterly we seldom find a case where these cannot safely be broken down.

We have learned from experience to know beforehand from the shape of the spleen which are difficult cases. A spleen very long from above downwards usually means a long pedicle, and can easily be tackled piece by piece; but a broad spleen, extending medially beyond the middle line, means a thick bunched-up pedicle in which the vessels are difficult to reach and secure individually. In these latter cases we throw a ligature round the whole pedicle, or at any rate the main mass of it, and after cutting off the spleen we tie the gaping ends of the vessels separately. Occasionally the tail of the pancreas is very closely involved in the pedicle, and once or twice in difficult cases the tip of this organ has been included in the ligature and removed, but no bad results have ever been seen from this. All our cases are anæsthetised with chloroform, preceded by an injection of morphia and atropine, and a rectal saline is given directly they are returned to the ward and repeated at intervals. There has been no serious trouble with hæmorrhage in any of our cases. There have not been any immediate fatalities, and the patients generally leave the table with a good steady pulse. The spleens removed have varied in size from 1¼ lb. to 12½ lb., the average being 3¾ lb. for the series.

Mortality.

The only other published results in this country which can be traced are those from the Egyptian Government hospital, which report 43 cases by various surgeons with nine deaths, a mortality of 20·9 per cent. In our series the total mortality has been 11, which is 15·7 per cent. The mortality in the first 40 cases was only 10 per cent., but this was unfortunately increased in the following 30 cases by the loss of two or three cases unexpectedly in 1923. Nearly all the deaths occur between the second and fourth day. One died ten hours after operation, due apparently to a ligature slipping as a result of violent vomiting and coughing. Two cases were lost through pneumonia, but this danger has been wonderfully lessened by the routine use of pneumococcal vaccine as a prophylactic. Most of the deaths were presumably due to a type of late shock in which the patient never seems to rally from the operation. There appears to be some unknown factor in certain cases of this disease when the heart, apparently normal, suddenly gives way, causing a quick and fatal collapse. This occurred recently in a patient who collapsed on the very day fixed for his operation, shortly before he was due to be taken to the operating table. This may help towards explaining some of the unexpected deaths. It is hoped that a further series of cases will show a still smaller mortality.

After-results.

It is very difficult to follow up cases among the Egyptian villages, but considerable trouble has been taken in attempting to do so. A fair number of old splenectomy cases have been traced and examined, and these have nearly all been found well and strong, many of them exceptionally so. In none of them has there appeared any sign of ascites—one of the late symptoms of the disease when left to pursue its course without operation.

Conclusions.

1. That splenectomy is the most satisfactory treatment of Egyptian splenomegaly.
2. That great care is essential in the selection and preparation of cases.
3. That the mortality is still high, but untreated cases so early develop extreme ascites that the operation is justifiable.
4. That a small degree of leucocytosis is not necessarily a contra-indication to operation.

Our thanks are due to our senior colleague, Dr. F. O. Lasbrey, for his coöperation in the work, his 14 operations being included in the above.

THE EFFECT OF
SPLENECTOMY ON THE PRODUCTION OF EXPERIMENTAL PURPURA.

BY S. PHILLIPS BEDSON, M.D., M.SC. DURH.,
ASSISTANT BACTERIOLOGIST, LISTER INSTITUTE, LONDON.

NUMEROUS observers have been struck by the large number of platelets which are present in the spleen. One has only to tease up a portion of this organ in citrate saline and examine the preparation, stained or unstained, to be convinced of this. In the course of some recent work on the genesis of the platelet (Bedson and Johnston, in the press) this fact was brought out in another and rather more striking manner. An anti-spleen serum had been prepared, and it was found that this serum, like anti-platelet serum (Ledingham, 1913 [1]), was capable of producing typical purpura hæmorrhagica in the animal. This purpurigenic power has been shown to be specific to platelet antibody (Ledingham and Bedson, 1915,[2] Bedson, 1922 [3]), so that from this it follows that the anti-spleen serum contains platelet antibody. The spleen, therefore, contains platelet antigen either in the form of the mother cells of the platelet, or mature platelets or both, and since suitable control experiments showed that this fact could not be explained by the free blood contained in this organ, one is left with two alternative explanations: (1) The spleen is rich in platelets because it produces these elements; (2) or the platelets collect in this organ, most probably with a view to their destruction.

Against the first hypothesis must be ranged the observation of Hess (1917)[4] that splenectomy in man results in an increase in the number of platelets in the circulating blood. A similar observation has been made by Crawford (1924)[5] in a case of acholuric jaundice, and recently, both in this country and in America, splenectomy has been performed in cases of purpura hæmorrhagica, with beneficial results. (For a review of the literature on this subject see THE LANCET, 1924, ii., 229.) It was thought that it would be of interest to determine in greater detail the effect of splenectomy on the platelet content of the blood, and further, the effect of this procedure on the course of experimental purpura produced by anti-platelet serum, in the hope of throwing some light on the rôle played by the spleen in the mechanism of this disease.

EXPERIMENTAL DETAILS.

A. *Effect of Splenectomy on the Platelets of the Blood.*

1. *Immediate Effect.*—Guinea-pigs were splenectomised, platelets counts being made before and at intervals after operation. Control animals underwent laparotomy only. The immediate result of the removal of the spleen was an immense increase in the platelet count. As soon as two days after operation the count had in many instances doubled, these high figures being maintained for at least ten days. No rise was observed in the controls. The result of the first experiment is given in Table I.

TABLE I.

10 ,, ...	1,593,000	1,360,000	543,000

G.-p. = Guinea-pig.

A similar increase in the platelet count has invariably been found to follow splenectomy, but no qualitative changes have been demonstrable in these elements.

2. *Duration of the Platelet Increase Following Splenectomy.*—The next point determined was the length of time that this rise lasted. It was found that three to four weeks after operation the count had fallen again to normal, as is shown by the following example (Table II.).

TABLE II.—*Guinea-pig, S. 6.*

Time of observation.	Platelets per c.mm.	Time of observation.	Platelets per c.mm.
Before splenectomy..	671,000	After splenectomy—

After splenectomy—		14 ,, ...	1,319,000
2 days	1,225,000	16 ,, ...	1,237,000
7 ,, ...	1,425,000	22 ,, ...	784,000

It must be obvious from these findings that the spleen plays little or no part in the production of platelets in normal extra-uterine life. On the other hand, the observed facts find a ready explanation on the assumption that the spleen is concerned with the removal of the effete platelets from the circulation and their ultimate destruction. On this hypothesis splenectomy would upset the balance between production and destruction and, as we know that the platelets are produced rapidly, this results in an immense increase in the platelet content of the blood in a very short time. Soon this function of the spleen is taken on by the phagocytic cells of other portions of the reticulo-endothelial system, the balance is once again restored and the platelet count falls to normal. Should this view be correct, then an interesting question arises: What is the rôle played by the spleen in the production of purpura? The immediate benefit of splenectomy in this condition, as evidenced by the disappearance of hæmorrhages, would indicate that it is in some way concerned with the mechanism of purpura. Is the spleen necessary to the production of this condition? In destroying the injured platelet does it liberate some toxic factor which acts on capillary endothelium, producing the lesions necessary for the occurrence of hæmorrhage? Or is the effect of splenectomy merely indirect, the increase in the number of circulating platelets being the important factor? The following experiments provide the solution to this question.

B. *Effect of Anti-platelet Serum in Splenectomised Guinea-pigs.*

This was first of all investigated in guinea-pigs which had recently had their spleens removed and which still had high platelets counts. They were given a dose of anti-platelet serum which invariably gave rise to typical purpura in normal animals of the same weight. It was found that though the serum was still capable of destroying the platelets in the circulation of splenectomised guinea-pigs, the majority of these animals showed *no hæmorrhages whatever*, whereas normal animals of the same weight and receiving the same dose of serum developed severe purpura. The findings in the first experiment are given in Table III.

TABLE III.

Date in 1924.	G.-p., S. 2 (350 g.).	G.-p., S. 3 (345 g.).	G.-p., S. 7 (control) (350 g.).

31/5	30,000 No purpura.	22,000	None seen. Very severe purpura.

* 0·5 c.cm. anti-platelet serum intraperitoneally.

The protection to anti-platelet serum is, however, merely relative, as some of the splenectomised animals which had received 0·5 c.cm. of the serum showed a moderate degree of purpura. As will be seen from Table IV., which summarises these experiments, five out of eight of the splenectomised guinea-pigs showed no purpura at all, whereas all seven control animals presented typical findings.

TABLE IV.

Moderate purpura..	1	—			
Total				8	7

All animals were approximately of the same weight. All received 0·5 c.cm. anti-platelet serum intraperitoneally.

In the next experiment (Table V.) a series of four splenectomised guinea-pigs received increasing doses of anti-platelet serum.

Here, again, the protection afforded by splenectomy is demonstrated, but the fact that it is not absolute is equally obvious. The series is somewhat spoilt by the fact that guinea-pig S. 10, which only received a dose of 0·5 c.cm., developed purpura. It must be pointed out, however, that this animal was the smallest, and was thin and in poor condition at the time of experiment. Leaving aside animal S. 10, it will be seen that by increasing the dose of anti-platelet serum the protection is overcome, though even S. 12 and S. 13 were to a certain degree protected, because they showed only moderate degrees of purpura with doses as large as 1·0 c.cm. and 1·25 c.cm. What, then, is the explanation of this protection? It has been shown (Bedson, loc. cit.) that two factors at least are essential to the production of experimental purpura: (1) absence or almost complete absence of platelets from the circulation, (2) some lesion of the capillary wall (endothelium).

TABLE V.

* c.cm. anti-platelet serum intraperitoneally.
—† = no platelets seen.

Further, experimental findings indicate that, on the introduction of anti-platelet serum into the animal body, the platelets are the first elements acted upon. Should the dose given be in excess of that required to destroy the circulating platelets, then the unused portion acts on the endothelium of the small vessels, producing that other change essential to the production of purpura. Thus in rabbits, using the intravenous route, it is possible so to grade the dose of anti-platelet serum as to produce partial destruction of the platelets of the blood without purpura, complete removal of the platelets again without purpura, and finally with a larger dose still complete destruction of platelets together with purpura. It would appear, then, that the protection afforded by splenectomy to anti-platelet serum was merely due to the increased number of circulating platelets. A dose of serum which in the normal animal would be sufficient to destroy the platelets and act on the capillary endothelium as well, in the splenectomised animal would be merely sufficient to destroy or considerably reduce the platelets, leaving none free to give rise to endothelial lesions. This suggestion is already indicated as the correct one from the experimental data recorded in Table V. However, since the platelet count returns again to normal three to four weeks after splenectomy, this point could be readily settled by testing the resistance of guinea-pigs which had been splenectomised at least one month and in which the platelet counts were again normal. This has been done and the result is given in Table VI.

TABLE VI.

Date in 1924	G.-p., S. 22.	G.-p., S. 23.	G.-p., S. 24.	G.-p., S. 25.	G.-p., S. 26.
	Platelets per c.mm.			Platelets per c.mm.	
27/6	Splenectomy.	Splenectomy.	Splenectomy.	—	—
6/8	864,000 —*	827,000 —*	764,000 —*	680,000 —*	761,000 —*
7/8	Platelets absent from circulation. Severe purpura.			No platelets seen. Severe purpura.	

* 0·5 c.cm. anti-platelet serum intraperitoneally.

Table VI. speaks for itself. It is quite obvious that the guinea-pig which has had its spleen removed and in which the platelet count has returned to the normal level again, reacts to anti-platelet serum in exactly the same way as the normal animal; it enjoys no protection at all. From this it follows that the spleen itself plays no direct rôle in the mechanism of purpura, and that the protection afforded by this procedure finds its explanation in the increase in the number of platelets in the circulating blood. It would also appear that the improvement brought about by splenectomy in cases of purpura hæmorrhagica could only be of a temporary nature. As soon as this function of the spleen is taken on by some other portion of the reticulo-endothelial system, the platelets will again disappear from the circulation and the purpura will return.

Conclusions.

(1) Splenectomy gives rise to a great increase in the number of platelets in the circulation. (2) In the guinea-pig this rise is manifest 48 hours after operation, reaches its maximum about the tenth–fourteenth day, and falls again to normal in three–four weeks. (3) Splenectomy in the guinea-pig affords a degree of protection to the production of experimental purpura by means of an anti-platelet serum. (4) The spleen s only indirectly concerned in the mechanism of this pathological state. (5) Splenectomy cannot be relied n to give any but temporary relief in the treatment f purpura hæmorrhagica.

Clinical and Laboratory Notes.

TOXIC INFLUENCES IN AN INSULIN TREATED DIABETIC.

By R. OWEN-JONES, M.R.C.S. ENG.,
HOUSE SURGEON, MIDDLESEX HOSPITAL.

IT has been stated that insulin has little or no action pon cases showing septic absorption, but in the light f the following case it would appear that massive oses are of distinct value.

The patient, a woman of 53, had an attack of intense pain t the site of some varicose veins about 4 inches above the ternal malleolus of the right leg in February. This area ubsequently became quite anæsthetic and assumed the ppearance of a superficial gangrenous slough. The condition owly spread downwards, and on June 5th, 1924, she was dmitted to this hospital. An examination showed dry angrene of the whole of the right foot and lower part of the g, the line of demarcation being 7 inches above the internal alleolus. The heel and distal part of the great toe of the ft leg were similarly affected. No popliteal pulse could be etected on either side, and the femoral pulse was not felt the right.

Urine examination showed 2 per cent. sugar, a total of 4 g. in 24 hours, acetone and diacetic acid also being resent. The blood-sugar was 258 mg. per 100 c.cm.; on nth day Allen's diet. She was then put on starvation diet, en first day Allen's, &c., up to tenth day diet, the insulin eing increased from 10 units twice daily to 25 units thrice aily. On twelfth day Allen's diet and 25 units insulin rice daily; her urine-sugar became 0·970 and the blood-gar 153 mg. per 100 c.cm.

On July 5th she was transferred to a surgical ward under r. W. Sampson Handley, who amputated the right leg the knee under open ether anæsthesia, and performed jection of the perivascular sympathetic trunks of the left moral artery with alcohol. The patient made excellent rogress for a week. The urine-sugar then became 3·3 per nt., Rothera's test and the ferric chloride test being rongly positive, and the blood-sugar 279 mg. per 100 c.cm. The insulin was increased to 225 units daily in three doses. he patient gradually became worse and the usual stimulants d to be administered hourly. The stump-flaps now showed gns of secondary infection; superficial sloughs and a very ee purulent discharge appearing, and the entire line of ture gaped. On July 27th the prognosis was considered peless; temperature subnormal, pulse 92, and the tient showed signs of developing a fatal diabetic coma.

Energetic treatment of the infected stump with eusol resulted in the separation of a large slough on the following day, the discharge diminished, and the wound appeared markedly cleaner. On this day the urine-sugar dropped to 1 per cent. although the insulin had not been increased, and by August 2nd the amount of sugar became 0·3 per cent., 0·2 per cent., and then nil. The blood-sugar had become 158 mg. per 100 c.cm. Throughout this period the diet had been No. 1 Allen's, and the insulin dosage 225 units daily. The strength of this insulin was 40 per cent. increase on the original Toronto (human) unit (i.e., one-third of the amount required to lower the blood-sugar of a starving 2 kilogramme rabbit to 0·045 per cent. within a period of four hours).

By Sept. 1st the stump was nearly healed, the gangrenous areas on the left foot separated off, and the patient's general condition was much better than when she had been admitted. On being discharged from hospital on Sept. 4th a slight amount of sugar had appeared again in the urine, but her stump was practically healed.

The case merits description as illustrating the marked influence of a septic focus upon the sugar excretion rate in a case under the influence of insulin treatment. So far as could be ascertained at the time, and in the light of the present limited knowledge of the conditions affecting the action of insulin, there were no factors other than the elimination of the septic focus to bring about this sudden change. It might be argued that the massive doses of insulin improved the patient's condition sufficiently to produce separation of the sloughs. Against this, however, is the fact that the insulin dosage had been the same for over a fortnight with no change for the better in the sugar amounts or in the wound. The sudden change from an almost comatose condition to one where the urine was sugar-free, induced by the separation of a slough and the free drainage of the stump, shows the marked effect of absorbed toxins upon the diabetic patient.

I am indebted to the Biochemical Department under Dr. E. C. Dodds for the estimations carried out, and to Mr. Sampson Handley for permission to publish the case.

LUPUS ERYTHEMATOSUS AND ALOPECIA AREATA.*

By M. G. HANNAY, F.R.C.P. EDIN., M.R.C.P. LOND.,
PHYSICIAN, ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN;
LECTURER, LONDON SCHOOL OF DERMATOLOGY.

THE cause of lupus erythematosus is generally supposed to be a toxin circulating in the blood. While I believe the majority of the French school still incline to the tuberculous nature of the toxin, the opinion is growing in other countries, and is firmly established here, that many other toxins are capable of causing the disease in predisposed individuals. The ætiology of alopecia areata is even more controversial, but the toxic theory has always claimed many adherents.

Barber [1] has produced evidence which tends to show that some cases at least of lupus erythematosus are due to toxic absorption from focal sepsis, and that a *Streptococcus longus* is the organism most often at fault. In another contribution, the same observer [1] reports several cases of alopecia areata associated with focal sepsis, which he believes was the cause of the disease in those particular patients.

If toxins of various kinds may be the cause of both affections a common factor becomes possible, and it will not be surprising to find the two coexisting in the same patient. The following case is an example of such a combination:—

The patient was a woman, aged 32, who first attended hospital in August, 1921, with several small patches of lupus erythematosus of the face of 12 months' duration. The general condition was good, tonsils were not enlarged, and there was no gross oral sepsis. The patient was treated mainly by applications of CO_2 snow, calamine lotion, and, internally, iodide of mercury. In May, 1922, it was noted that the patches were paler, but fresh ones had appeared. Early in August of the same year there appeared on the scalp several typical patches of alopecia areata, which rapidly extended until more than half the total area of the scalp was completely bald. Cultures were taken from the mouth, naso-pharynx, and fæces, and growths of *Staphylococcus aureus* and *B. coli* obtained. A vaccine containing these organisms was given on August 11th, and continued in weekly doses. In October two doubtful stumps were removed. In November a streptococcus was isolated from the naso-pharynx and added to the vaccine. By this time the hair had begun to grow in all patches; it continued to grow rapidly and did not fall out again. At the same time there was a marked improvement in the face lesions of lupus erythematosus, although these did not completely disappear.

---

* Readers will notice with regret the announcement of Dr. Hannay's death on p. 1154.—ED. L.

The clinical appearances of lupus erythematosus and alopecia areata are well known, and typical examples give rise to no difficulty in diagnosis. From time to time, however, cases are met with which are not typical of any familiar disease of the scalp, but which, on close examination, present features which might be regarded as intermediate between the two conditions. I have even known one case which was seen by two skilled dermatologists and pronounced to be lupus erythematosus by one of them and alopecia areata by the other. The lesions in such cases may be single or multiple, and are usually about an inch in diameter. The area is bald, or nearly so; there may be a few stumpy atrophic hairs at the margin, but as a rule typical "point of exclamation" hairs are absent. The patch may show an erythematous flush, and possibly a very slight degree of atrophy. While not showing the follicular plugs, or little pits characteristic of lupus erythematosus, each follicle remains obvious. A certain amount of pruritus may be present. Sometimes the erythema is more marked, there is slight hyperkeratosis of the mouths of the follicles, with a suspicion of a little dry scaliness, and the case passes into the category of lupus erythematosus. On the other hand, the patch may be more smooth and less erythematous, and one is able with more confidence to apply the label of alopecia areata.

A patient under my care at St. John's Hospital was diagnosed by his doctor and by my assistant as a case of alopecia areata. On examination there were areate patches in which the hair had fallen out, but there was some redness, and a very slight scaliness which caused some doubt as to the nature of the case. The lesions are acquiring the aspect of a mild lupus erythematosus.

Dr. L. Chatellier,[2] in 1922, reported an interesting case of subacute lupus erythematosus with total alopecia. The patient was a woman aged 29. In 1919 she first noticed some reddish scaly and slightly irritable patches on the scalp. The hair fell out in these patches very quickly. Eighteen months later the scalp became red, and the hair came out "en masse" within two weeks. Later on there were general symptoms, with an eruption of lupus erythematosus on the body. The scalp was bright red, but *smooth*, with no trace of seborrhœa or scaliness.

In commenting on the case, the author remarked that alopecia is rare in this connexion, but had been noted by Jadassohn, Fox, Roth, Pernet, and Verotti. In Verotti's case the scalp was smooth and not inflammatory, and he is quoted as saying that it seemed possible to meet with cases of subacute lupus erythematosus in the course of which a total alopecia develops, with or without apparent lesions of the scalp. In Short's[3] case (quoted by Pernet and included by him in his series of cases of Lupus érythémateux aigu d'emblée) the hair fell out, but there was no inflammatory reaction present in the scalp. In borderland cases or where the two diseases are frankly associated every effort should, of course, be made to find and eliminate the offending toxin.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

A MEETING of this section was held on Nov. 14th, Sir ARNOLD LAWSON, the President, being in the chair.

Mr. RANSOM PICKARD read a paper on the

Relation between Cavernous Atrophy and Glaucoma.

He said that his object was to show that cavernous atrophy was a distinct entity, its association with glaucoma being merely casual, not causal. Cavernous atrophy might occur without glaucoma. He detailed seven cases, none of which had any nerve symptoms apart from the condition of the optic nerves. The discs were pale where the lamina cribrosa was exposed, but not elsewhere; the vessels were not contracted. In none of the cases cited was a tension of more than 28 mm. of mercury found; in most of them it was well below this. The progress of cavernous atrophy was very slow, and it seemed to become stationary after reaching a certain degree of intensity. In distinguishing cases of the condition from those of tru glaucoma a careful study of the colour fields was very useful.

Mr. MALCOLM HEPBURN said the signs in the tw kinds of case were so similar that he would hesitat about abstaining from suggesting operation in case o a mistake being made.

Mr. G. H. POOLEY regretted that Mr. Pickard ha not given histories showing the progress of the seve cases related. A very important feature was th progress or otherwise of the condition.

Mr. LESLIE PATON referred to one undoubted cas of cavernous atrophy which had come into his experience, and that was 15 years ago, and was seen befor Schnabel wrote on the subject. The patient had bee previously under Mr. Priestley Smith's observation and he, with his well-known acumen, noted that though the condition resembled glaucoma in man ways, and had a very deep cup, it was not glaucoma The patient had myopia to the extent of 15 D. Mr Paton's first observation on the patient showed tha the field was limited to the 10° circle, and th last field taken, many years afterwards, showed n change from that.

Mr. PICKARD, in reply, said he had been trying fo years to meet with and study early cases of glaucoma and it was thus he came to recognise instances o cavernous atrophy. Several of his cases had bee carefully watched for some years, and they showed no progress. One could not tell by examinin a case whether it would be of short or long duration He did not think these cases were of commo occurrence.

Dr. FREELAND FERGUS (Glasgow) read a paper on

Miners' Nystagmus: Its Diagnosis and Origin.

He said that in ordinary cases of the conditio diagnosis was not difficult. The oscillatory movement of the eyeball were not always present, but there wer frontal and occipital headache, tremors of the head vascular disturbances, photophobia, vertigo, an usually a history of the onset of visual disturbances This, he thought, suggested a wide involvement o nerve centres. Photophobia was sometimes absent but visual acuity was practically always reduced and this latter was of considerable value in cases i which the diagnosis was doubtful. One such doubtfu case was that of a miner in a district which showe little nystagmus. This man was certified, some year ago, as having miner's nystagmus by both the examining surgeon and the referee who examined him o appeal. Recently the diagnosis was questioned and then it was found that the man's condition ha altered considerably; he was using a stick for gettin about, and was suffering from disturbance of innerva tion of some of the leg muscles. There were neither head tremors nor photophobia, but the patellar reflexes were exaggerated and ankle clonus was absent. No oscillatory movements of the eyes were evident on examination, and the positive range of convergence for the median position was excellent; but on extreme upward fixation there was definite diplopia. The pupils reacted regularly, though somewhat sluggishly, to light; there was no ptosis. There was no serious error of refraction, nor could he find tremulous movements in either eye, and their fundi were healthy. In each eye the visual acuteness was practically 6/6. There might, he said, be nystagmus with diminished visual acuteness without the case being one of miners' nystagmus. Still, given a mine-worker with nystagmus and diminished vision, the evidence of the presence of other causes of nystagmus must be satisfactory before a negative conclusion as regards miners' nystagmus was arrived at.

Visual acuteness in miners' nystagmus might be due to one of two causes, or to a combination of them. The first was, that the rapid movements of the eyes prevented the proper stimulation of the maculæ. In the second place, it must be remembered that there was, in almost all cases of the disease, considerable pain at the back of the head, and this might indicate a lesion at the pole of the occipital cortex, involving the centres concerned with visual acuteness. In one of his cases the man had excellent vision, and a certifying surgeon diagnosed the case as miners' nystagmus. With that the speaker could not agree. Only the left eye was said to be affected, and the man had been away from work four months. Diplopia was permanently present, due to an affection of the eft eye, the vision of which was 6/6 (Snellen). The man had been operated upon for ethmoidal disease. There was no photophobia, no head tremors, and the man had not seen lights appear to revolve. In certain parts of the upper field of fixation there were to be seen those jerky movements which had received the name "pseudo-nystagmus." Dr. Fergus did not consider that miners' nystagmus had yet been satisfactorily explained. It did not seem to be due to either posture or defective illumination, nor to the depth of the pit in which the men worked. He had seen cases from pits which were comparatively shallow. Dr. F. Robson, of Penarth, who had conducted an admirable statistical research, attributed it to working in certain soft kinds of coal. Still, cases of it did occur in workers on hard and bright coal. A considerable number of cerebral centres eemed to be involved in the disease and those centres were probably coördinated to each other. But the causal agent did not seem to affect any entres in the medulla or cord. He had thought it might be due to a definite and specific microorganism, and this might explain cases of the condition being more abundant in some districts than in others. n support of the idea was the fact that miners' ystagmus was accompanied by a good deal of contitutional, and even mental, disturbance. He was ot aware of any post-mortem examinations having been made on cases of the disease. If such, with bacteriological examinations, were made, much light might be thrown on the subject. The blood and erebro-spinal fluid might be examined in living ubjects. The Ministry of Health, he suggested, might rrange for a competent set of men to make a careful nquiry into the matter, including an investigation of he sanitary condition of the pits where it was revalent.

The **President** said the views and suggestions dvanced by Dr. Freeland Fergus were counter to the sually accepted ideas concerning miners' nystagmus. n discussions which had been held on the subject efective illumination seemed to be agreed upon as he main cause, and it had been stated that when he illumination of a mine was improved, the incidence f nystagmus among the workers in it diminished. The idea now advanced that it might be toxæmic, nd not a disease specially of the eyes, opened up a arge field for thought.

Dr. F. **Robson** (Penarth) pointed out that in some coal areas in Scotland there was coal-miners' nystagmus, while in other mines all the nystagmus cases were among the men working particular seams, yet all the men were working under the same general conditions as to temperature and depth. The varied incidence seemed to be attributable to the particular environment, not to personal idiosyncrasy among the workers nor to the amount of light used. Curiously no nystagmus was reported as occurring in the coal-mines of America and those of South Africa. The disease was, however, quite frequent in New South Wales, where coal was liable to spontaneous combustion, the worked coal left for even a single shift getting quite hot. He thought the liberation of CO_2 might affect the neurons by a general lowering of the worker's vitality. Usually American mines were quite shallow, some not more than 500 feet deep, and they were excellently ventilated. This could not be said of our own.

Dr. C. F. **Harford** urged that the psychology of cases believed to be miners' nystagmus, and who ceased work because of it, should be studied.

Mr. G. H. **Pooley** (Sheffield) referred to the long-continued study of the disease which had been carried out by Romiet, of Belgium, who found that after the illumination of pits was improved there was a definite diminution in the amount of miners' nystagmus. Investigations carried the lesson that claims for compensation constituted no evidence of the incidence of the disease. Statistics should be based only on an examination of all the men in the mines under review. In the condition the eye movements were always definitely undulatory, not a slow movement in one direction followed by a quick return, as seen in labyrinthine nystagmus. As to the bacterial theory, he had no doubt that coal-workers more often had wounds of the cornea infected than did steel-workers. Dealing with the psychological aspect of the subject, he said he divided the neuroses associated with miners' nystagmus into two definite groups. The first were the cases mentioned by the older writers. In these the neurosis was most intense before the man ceased work, but improved rapidly within three months of leaving the pit. But now, after men had been away six months, many developed a neurosis of a different nature, and this placed them in the second category. The longer the man was kept under observation and examination, the worse he became. He had seen cases lasting ten years who were miserable wrecks, and this he attributed to the fact that they were receiving monetary compensation.

Mr. **Harrison Butler** said he had seen several cases of well-marked miners' nystagmus with quite good vision. If errors of refraction were corrected and the test-types placed below the line of the eyes, it would be found that many of the subjects of this condition could see well.

Mr. R. J. **Coulter** (Newport, Mon.) expressed his agreement with Mr. Butler, but did not agree with Mr. Pooley that corneal lacerations in miners did badly.

Mr. **Bernard Cridland** (Wolverhampton) said one important sign of miners' nystagmus was impaired visual acuity. With regard to the idea that the condition might be due to cerebral disturbance in the occipital region, spasm of accommodation coupled with poor vision had to be taken into consideration. The close anatomical association between the centre for memory and that for vision must be remembered in considering the part played by the cerebral cortex. Prof. J. S. Haldane had ruled out carbon-monoxide poisoning as a cause of miners' nystagmus, yet the condition was absent in candle-lighted mines, but not in those lighted by lamps. If the atmosphere of a mine would not allow a candle to burn, the man who worked in it must suffer in health. The ideas put forward by Dr. Robson deserved every consideration.

Dr. J. W. **Thomas** suggested an investigation of the relationship between the incidence of miners' nystagmus and the physical characteristics of the coal face being worked. Soft coal was uniformly black and dull, reflecting practically no light. Electric cap-lamps illuminated the coal face a hundred times better than did the other kinds of lamps used underground.

Dr. Fergus briefly replied.

Exhibition of Cases and Specimens.

Mr. Basil Lang showed three patients. The first had an implantation cyst which occurred after an ordinary advancement operation. The second had, apparently, congenital pigmentation in the deep retina or the superficial choroid. The third patient received a blow over an eye and it subsequently became blind. He thought it might have been a typical choroido-retinitis.

Dr. Rosa Ford exhibited two cases of congenital ankyloblepharon—namely, in a father and his child. The father, who was now aged 34, was operated upon when 4 years of age, and at the present time experienced no disability. The child had the external canthi slit last July, and had since been able to open its eyes much better, and did not raise the lids so much in the effort to see.

Miss Ida Mann showed, by means of the epidiascope, a series of slides to illustrate the development of the eye at different stages of uterine life. She noted that in the case of the father now shown the levator palpebræ superioris was absent. Probably there was a similar absence in the child, but she was a difficult patient to examine.

Mr. A. H. Levy showed two cases of acute macular disease. The first was a boy, who at first had complained of little failure of vision, but in the ensuing three months hæmorrhage occurred, with exudate of the whole macula. The other patient was a girl, aged 18, who, in the last month, had developed a patch on the macula in the left eye, with hæmorrhage, and he was not sure as to the nature of it. Wassermann and von Pirquet tests revealed no clue to the ætiology, neither had other examinations nor the history.

SECTION OF PATHOLOGY.

A meeting of this section was held on Nov. 18th, Dr. J. A. Murray, the President, being in the chair.

Dr. Thomas Lumsden communicated some observations on

Cancer Cells in Vitro.

Normal tissue cells cultured in pure serum (pH 7·4 to 7·7) grow freely and divide by typical mitosis. Cancer cells, on the other hand, migrate very actively and enlarge individually, but they only rarely divide, and then chiefly by amitotic nuclear fission. The addition of embryo, autolysed tissue, or tumour extract does not either increase or diminish the growth of normal or tumour cells so long as the original fragment is present, except in so far as they act as buffers should buffering be required. No medium is at present available in which cancer cells can be cultivated indefinitely, but for the study of surviving tumour tissue serum is a convenient and satisfactory medium. The serum must not be kept for more than three weeks, since after that period, even if preserved in sealed capillary tubes, the serum deposits "asteroids"—i.e., stellate crystals of calcium salts of the fatty acids, and is then useless or harmful. Cancer cells surviving in serum are all actively amœboid; some degenerate rapidly setting free many naked nuclei, others progressively enlarge and become highly resistant to infections and other adverse conditions. Thus, cells which had been severely bombarded with γ radium rays for an hour and a half were uninjured thereby, and continued to move about actively for over a week. These large cancer cells still survive even if not re-fed for eight days, which indicates that they are not easily killed by their own waste products and that they need but little food or oxygen for a bare subsistence. Neither the presence of normal tissues nor of red blood corpuscles alters appreciably the behaviour of these cells in serum. In such symbiotic cultures normal tissues do not grow more actively than usual, which fact does not favour the view that cancer cells contain a special growth factor for normal tissues.

The President made a communication on

Increased and Diminished Resistance to the Induction of Cancer.

Animals in which cancer has developed spontaneously or as the result of tarring the skin are much more refractory to the carcinogenic action of tar than normal animals. If the second tarring be begun before cancer has developed from the first tarring, a second primary carcinoma can be produced in practically every case, and the time necessary is less than in the first instance—i.e., about the time the first primary carcinoma comes up the whole animal is in a state of greater susceptibility to the carcinogenic action of tar. Certain puzzling features of cancer in man (rarity of multiple primary cancer, late regional recurrence after operation and some statistical difficulties) fall into a rational sequence if we assume a phase of diminished refractoriness followed by a phase of increased refractoriness in the development of cancer in the human subject.

Mr. A. Fleming read a paper on the Effect of Various Chemicals on the Leucocytes.

MEDICAL SOCIETY OF LONDON.

The Treatment of Senile Gangrene.

A meeting of this Society was held on Nov. 24th, Dr. Eustace M. Callender, the President, being in the chair.

Sir Anthony Bowlby introduced a discussion on the treatment of senile gangrene. He said the first complete clinical description of the disease was that given 160 years ago by Dr. Percival Pott, whose name is associated with Pott's disease of the spine, Pott's fracture, and other conditions, and who was one of the teachers of John Hunter. Pott said senile gangrene was unlike the mortification from inflammation, that from external cold, from ligature or bandage, or other known and visible cause. In a few cases it made its appearance with little or no pain, but in most cases the patient felt great uneasiness through the whole foot and ankle-joint, particularly during the night, even before the parts showed any marked distemper. The first discoloured spot usually occurred at the end of one of the little toes or on the inside of one of them. From this spot the cuticle was always found to be detached, the skin beneath being of a dark red colour. The progress of the condition varied in different subjects and under different circumstances. When it spread to the upper part of the foot it was shown by tumefaction and change of colour, sometimes by vesication, but wherever it appeared one of the first marks was a detachment of the cuticle. Pott saw 20 males with it to each female, and more often in the rich than in the poor, and in great eaters than in excessive drinkers. It frequently happened in advanced life, but was by no means confined to old age. Pott thought he had observed gangrene most in those who had had flying pains in the feet which had been regarded as gout, but seldom in persons who had gout "regularly and fairly." Sir Anthony Bowlby said he would take Pott's description as the text of his remarks, since it held good to the present day as the record of a careful clinical observer.

Diffuse Obliterative Arteritis.

It was necessary to consider the forms of gangrene which were due to alterations in the calibre and in the walls of vessels, sometimes called diffuse obliterative arteritis, sometimes intermittent claudication. Cases with diffuse thickening of the vessel walls occurred in quite young subjects, and the subjects of this condition seldom lived to any considerable age. In an enormous proportion the subjects of it belonged to the Semitic race, especially those from Russia and Poland. This fact made one wonder what was the cause of this selective incidence. When in 1919 Sir

Anthony Bowlby was in New York he was told that there were under care more than a hundred such cases, many of them children, and most of them came from one of the countries named. In practically all there was a gradual closure of arteries, and not merely of the toes and feet, but of hands, fingers, nose, and ears. In intermittent claudication there was but little tendency for the disease to proceed to absolute gangrene. He knew a man with marked defect of circulation which he had had for 20 years and was no worse now than when the condition commenced. So long as this patient kept his feet up he was comparatively comfortable. Still, he could only walk a short distance without beginning to suffer pain, which soon became unbearable; he was thus largely confined to a recumbent posture.

Varieties of Senile Gangrene.

Senile gangrene could be said to occur mainly n three classes of conditions. The first was that of the old or elderly man whose circulation had never been good, who had suffered from coldness and numbness of feet, and who suddenly got a swollen, discoloured, and painful foot. That was a form not ncluded in Pott's description. The next was that described by Pott, in which the condition began in one or more of the toes, often symmetrically, but more frequently the toe or toes of one foot, thence slowly spread to another toe, and in a week or two or a month spread to another toe. As each toe became affected it shrivelled and died, but all the ime only the toes were involved. A third class of case was that in which the disease began in the toes and spread somewhat quickly from toe to toe, then, n a few days or weeks, to the foot itself.

Sir Anthony Bowlby said that, in his opinion, in every case of definite senile gangrene, one or both ibial arteries were occluded, mostly calcareous. This was not believed in by Pott. A skiagram of a case showed the arteries as calcified and well-defined ines. This calcification and occlusion of the main arteries of the leg seemed to him to be the chief cause of senile gangrene. How could the case be explained which came on suddenly? The sudden occlusion of he artery carrying a certain amount of blood had caused the sudden attack.

Management of a Case.

If this occurred in an old man it was not wise to ump to the conclusion that the condition would necessarily spread, nor that it would not. He knew cases in which a very definite opinion had been given hat amputation should be done, but that was not any more true than that a case of embolic gangrene equired that operation. The right course was to wait and see to what extent the collateral circulation was capable of dealing with the part. A very few days would decide the point. It was not a case of gangrene spreading from toe to toe, but one in which he whole foot was swollen, discoloured, and cold. Yet it might have retained its sensation, and if that were so there was no need to conclude that immediate amputation was indicated. In the second class of ase also, in which the gangrene began in a toe and pread from toe to toe very slowly, he did not hesitate to counsel waiting. In most of the cases of he kind the part was dry; it was a more serious matter if the condition was a moist one. With regard o the third class of case, he laid down for himself a ule many years ago—namely, that where senile gangrene was not limited to the toes, but spread to he dorsum of the foot, amputation should be carried ut without delay. While waiting, in the first two lasses of case, what could be done for the relief of he patient's pain and discomfort? Pott found that Peruvian bark was useless in this condition, though t was the custom to use it, and he tried, with much uccess, opium as a fomentation and in other ways. t caused the tumefaction to subside and the parts o separate with less pain. Sir Anthony Bowlby had found nothing better than opium for these cases. t dilated the capillaries and materially aided the irculation of the blood through neighbouring vessels, and so expedited the setting up of a collateral circulation to the damaged part.

Sympathectomy and Alcohol Injection.

Within recent years sympathectomy (Larish's operation) had been advocated and carried out. It consisted of clearing the trunk of its main artery in Scarpa's triangle and of all its cellular tissue, and removing the sympathetic branches. A modification by Mr. Sampson Handley consisted of the injection of absolute alcohol. Sir Anthony Bowlby had not tried those methods, and hoped they would be discussed.

It was agreed that the diseased part should be kept dry by means of antiseptic powders, which were greatly preferable to moist dressings; and that the whole limb below the knee should be kept warm and raised in bed.

The Question of Amputation.

If the first class of case (with thrombosis) did not clear up in a short time, a large, swollen and gangrenous foot would result, and it must come off. And in the third class of case, that in which gangrene began in the toes and spread to the dorsum of the foot, he counselled immediate amputation, but would like to hear the point discussed. At what level should the amputation be carried out? The old Syme operation, amputation at the ankle-joint, was not to be encouraged. It must be remembered that in all cases there was a large flap which took much nourishment, and was difficult to keep in good condition. He considered that the Syme operation for these cases had nothing to recommend it. Should one operate below the knee or above it? The superficial femoral artery was mainly for the supply of the leg below the knee, and the tissues above the knee were supplied mainly by the profunda femoris and branches, which came in from the sciatic, gluteal, and obturator. Those vessels in the thigh were generally free from calcified conditions. The thigh would be well nourished and able to repair damage done by amputation. Therefore he felt it was better to amputate immediately above the knee; there was nothing to be gained by going far above the knee. There was objection to operating in the upper part of the leg, for the flaps which were cut were likely to be insufficiently nourished by the damaged tibials. A further objection was that if the arteries were calcified there was a real difficulty in securing them. A skiagram would often indicate which arteries were calcified and which were not. If there was calcareous degeneration of the popliteal low down, it indicated that one should go higher up for a healthy vessel to ligature. If the tibial arteries were calcareous throughout, it was doubtful if there could be satisfactory ligature of them in the leg. Therefore, if the worst came to the worst, one would amputate in the thigh. But he had seen satisfactory results from amputation in the upper part of the leg.

Discussion.

Mr. W. SAMPSON HANDLEY did not question the broad truth of Sir Anthony Bowlby's statement that senile gangrene was due to fixed organic changes in the arteries, but suggested that in many cases there was superimposed a nerve element, an element of spasm or vaso-constriction. By Larish's operation of sympathectomy the outer coat of the femoral artery was removed for a centimetre or so, which gave a vaso-dilator effect in the limb below, and the effect lasted a considerable time. It occurred to the speaker that a similar result could be attained more simply by injecting pure alcohol into the outer coat of the artery. He showed drawings of the case of a woman, aged 69, who had senile gangrene in the right foot, the symptoms having commenced ten days before admission. The lesions were on the dorsum and on the plantar surface of the foot, the gangrene extending some distance along the metatarsals and the tarsal and plantar aspects. No pulsation could be felt in any of the arteries of the right lower limb, even in the femoral. The temperature was never above 99° F. He injected alcohol into the superficial femoral. On the day following the injection the patient said she was more comfortable, and there was seen an opaque whitish band round the diseased area. Just previously to the injection the pain had been increasing. A week later the area which had been black was found to have recovered its normal colour, and the surface thermometer showed the diseased foot to be 2° warmer than the healthy one. The toes finally dropped off, and the illustration exhibited showed healthy-looking tissue; it had remained so. He had tried the same treatment in cases of Raynaud's disease, and in Bürger's disease, the condition which occurred in Polish Jews. He wondered whether the eating of rye bread had anything to do with the liability of these people to the disease. He thought there was a case to be made out for the occurrence of a spasmodic factor in senile gangrene, and the use of alcohol injection, even if it did not obviate amputation, might enable it to be done safely lower down the limb.

The PRESIDENT asked what could be done to stay gangrene when it was threatened. He quoted a case of his own in which, in a man aged 85, it supervened after influenza and pneumonia and prolonged lying in bed. Perhaps some such method as citrating the blood could be employed. The patient referred to lost four of the toes off the affected foot, but he lived three years longer.

Dr. PARKES WEBER spoke of premonitory symptoms of senile gangrene, such as intermittent claudication, and said Sampson Handley's method seemed admirably adapted to preventing this disease. In intermittent claudication, when both lower extremities were affected and there was nothing like erythromelalgia, the disease, he thought, was high up, either in the abdominal aorta or in the iliac arteries, and it was of the nature of atheroma, or atheroma with sclerosis.

Mr. J. E. H. ROBERTS accepted Sir Anthony Bowlby's definition of senile gangrene, and referred to the frequency with which calcification occurred at the bifurcation of the popliteal. He also spoke of the need for great care in handling the arteries, because of the great risk of cracking them. In thrombo-angeitis obliterans it must be remembered that the viscosity of the blood was considerably raised. Moreover, in most cases of senile gangrene there was a good deal of sugar in the urine, but after the gangrenous area was removed the sugar disappeared. If Mr. Sampson Handley's operation was applicable, it was especially so when the premonitory symptoms occurred.

Reply.

Sir ANTHONY BOWLBY congratulated Mr. Sampson Handley on the very successful case he had described and illustrated. But he thought that probably it was a case not of senile gangrene but of lodgment of an embolus in the femoral artery, especially as the onset was sudden and all the vessels there were pulseless. Still, whatever the cause, there was no doubt the injection of alcohol was very beneficial. With regard to what could be done in the early stages to prevent an extension of the gangrene, he was still of the opinion that opium was far more beneficial than any other method he knew; it improved the collateral circulation, and the patient felt the advantage of it for many months. With regard to the presence of sugar in the urine in these cases, he did not think it was sufficiently appreciated that in a large proportion of all the cases of senile gangrene there was a temporary glycosuria, and many such he had seen diagnosed as diabetic gangrene. Mostly it was a wrong diagnosis, and when operation—amputation or other—had been carried out, there was no longer glycosuria. These patients did not experience the characteristic thirst, nor the dry cracked tongue, nor did they pass the large quantities of urine which patients did with that disease. Of course, the prognosis in the non-diabetic cases was much better than in the diabetic. In the former class the condition of the tissues did not preclude amputation. In the true diabetic cases with gangrene it was usually of the moist variety; the patient had little or no resistance to the sepsis, and in the majority of cases the patient died before very long. He therefore insisted that it was of great importance to draw a distinction between cases of gangrene in patients with diabetes, and those who merely had sugar in the urine as a concomitant of the local disease.

MANCHESTER PATHOLOGICAL SOCIETY.

A MEETING of this Society was held on Nov. 12th, when Prof. W. W. C. TOPLEY delivered his presidential address on

Streptococci in Relation to Human Disease.

He pointed out that streptococci must be regarded as the first amongst pathogenic organisms as a cause of death in man and particularly in association with affections of the respiratory tract. Classification of such organisms was difficult and any classification must necessarily be inaccurate. A classification suitable for ordinary purposes was suggested. The influence of secondary streptococcal infection in influenza and measles was emphasised, and stress was laid on the importance of isolation and careful nursing precautions to prevent the spread of pneumonia in these cases. The mass of clinical and experimental evidence, he said, was overwhelmingly in favour of scarlet fever being a primary streptococcal infection; in the case of rheumatic fever, though the evidence was by no means so definite, there was much to support the view that a streptococcus was responsible. The pneumococcus group was considered, and Prof. Topley suggested that the Type I. antiserum appeared to be of definite therapeutic value. The decision as to the efficacy of pneumococcal antisera could only be arrived at by careful combined clinical and bacteriological investigation of a large number of cases.

NEWPORT MEDICAL SOCIETY.

AT the first clinical meeting of the session Mr. R. J. COULTER, the President, being in the chair, Dr. T. I. CANDY read a short communication on the

Treatment by X Rays of Menorrhagia due to Uterine Fibroids.

The type of case he considered best suited for this method of treatment was menorrhagia occurring in a patient over 40 years of age causing weakness and impairment of the general health and postponing the onset of the menopause. It was necessary to exclude the presence of malignancy and suppurative pelvic conditions. His technique was to administer at one sitting the dose necessary to produce amenorrhœa. The improved methods of measurement now available and the increase of knowledge of the biological action of X rays enabled this to be done with a considerable degree of precision. He found that the optimum time for treatment was within the first few days after cessation of menstruation. The next menstrual period came on as usual but always very much reduced in quantity. Thereafter complete amenorrhœa became established. In each of the 12 selected cases which he had treated the clinical results had been all that could be desired.

In the discussion which followed Dr. GLYN MORGAN, Dr. H. R. BURPITT, and Dr. MORRELL THOMAS took part.

Exhibition of Cases and Specimens.

Dr. MORRELL THOMAS showed an interesting pathological specimen of a case of hæmatometria following pregnancy.

Dr. CARVETH JOHNSON showed a case of aneurysm of the femoral artery associated with dilatation of the aorta.

Mr. R. J. **LEE** reported upon an interesting case of sarcoma of the upper jaw in which the growth retrogressed in a remarkable manner without treatment but which subsequently recurred. The diagnosis had been confirmed by pathological examination.

The **PRESIDENT** showed a small piece of fine copper wire which he had removed from the vitreous of a patient who had been struck on the eye by a clod of earth.

Dr. P. C. P. **INGRAM** showed a case of gumma of the upper lip successfully treated three years ago and which now showed, on X ray examination, extensive deposits in both lungs. Physical signs were few and it was thought to be a case of syphilis of the lungs.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on Nov. 5th, Sir **DAVID WALLACE**, the President, being in the chair.

Mr. A. H. H. **SINCLAIR** made a communication on

Intracapsular Extraction of Senile Cataract.

The speaker began with a quotation from Mackenzie's text-book of 1854, stating that there are three methods for the cure of cataract: 1. The removal of the cataract from the axis of vision. 2. The extraction of the cataract. 3. The division into fragments. It was pointed out that in the paper he wished to deal with the extraction method, in the case of senile cataract only, and by the intracapsular method in which the lens is removed complete in its capsule. Historical facts were next given, including a description of Hermann Pagenstecher's operations. The principal pioneer, he said, of the intracapsular method in modern times was Colonel Henry Smith, who began his work at Jullundur, India, in 1895 by the capsulotomy method, but having seen the intracapsular method performed by Malronez at Amritsar, became a convert to the latter method. He developed the operation on his own lines, now so well known, but stated then that the method was unsuited for juveniles.

Briefly the technique was as follows: A large incision was made with a Graefe's knife, no atropine was used and iridectomy might or might not be performed. The lens was expressed by pressure on the lower margin of the cornea by a blunt hook, either straight out or turning over in its delivery according to how the pressure was applied. Commenting on the method, Mr. Sinclair believed it to be the best in many cases, but it had to be used with great care in this country, as in many cases the zonule was very strong. A further method was described: to avoid strong pressure the extraction of the lens in its capsule effected by the application of a small vacuum pump. This method, though successful in the hands of the originators, Hulen and Barraquer, had not proved so successful in the hands of others. The suction of the best of vacuum pumps was unsteady, and the risk of the loss of vitreous was greater. Yet another method, that employed by Mr. Sinclair himself, was performed with the aid of blunt capsule forceps, for the purpose of grasping the capsule and withdrawing the lens. This method was used by Kalt, of Paris, in 1910, who designed the forceps known by his name. This method was studied by Stanculeanu, who performed a narrow iridectomy; he also examined the capsule before operation with a view to judging its toughness and its capability of standing the strain of traction. Knapp of New York, who had used the method since 1911, employing Kalt's forceps, had published a summary stating that in ten years' experience he had not found late deterioration or change which might be ascribed to the method of operation; further, there had been no vitreous changes, updrawn pupil, or iris prolapse.

Mr. Sinclair proceeded to describe his own technique. The lens was first carefully examined and the type of cataract determined as far as possible. At the operation, after a large incision, iridectomy was first performed followed by insertion of forceps, first opening and then closing with slight pressure against the lens; in this way a fold of capsule could be firmly grasped. Gentle forward traction was first employed, then, after a pause, traction was made in different directions upwards; this caused the suspensory ligaments below to give way one at a time; this step took about 30 seconds. After this the lens became pear-shaped and could be delivered with comparative ease, complete in its capsule. The forceps employed were a modification of Kalt's; they were large-bladed and toothless, slightly curved and provided with a hollow into which the capsule tissue was bunched, thus rendering the grip more efficient.

Regarding results on all cases (52), 16 obtained 6/6 vision; 18, 6/9; 6, 6/12; 7, 6/18; 2, 6/24; 2, 6/36, one case with 6/36 vision had retinal hæmorrhage at the macula and one case lost the sight of the eye from severe infection. Vitreous loss occurred in seven cases; vision in these was 2, 6/9; 2, 6/18; 2, 6/24; 1, 6/36; improvement in vision took place later. In 18 cases the capsule ruptured, leaving remnants in the eye as in the capsulotomy method. In three cases the forceps failed to grasp the capsule over a swollen lens and capsulectomy was performed. Concluding, Mr. Sinclair remarked that this was the least traumatic of the intracapsular methods, and the apparatus was of the simplest. The paper was illustrated by numerous lantern slides and was concluded with a kinematograph demonstration of the whole operation.

Discussion.

Dr. W. G. **SYM** said he preferred the usual capsulotomy method, though undoubtedly the intracapsular method avoided the possibility of having to needle remnants afterwards; on the other hand, with the capsulotomy method, the anterior capsule could be removed and no iridectomy had to be performed.—Dr. J. V. **PATERSON** pointed out that this intracapsular operation was the ideal one, but was attended with such grave danger that continental papers said that it was appalling and ought not to be allowed. In the hands of a highly skilled surgeon the operation was eminently successful, but the risk was too great to be undertaken unless by the most highly skilled.—Dr. E. H. **CAMERON** also spoke.

Dr. **CRANSTON LOW** gave a communication on

Immunity and Sensitisation in Ringworm and Favus.

He stated that, although ringworm was very common in this country, little attention had been paid to changes in the body as a result of infection. He proceeded to review the work on the subject which had been done, especially in Germany and Italy, during the last 20 years, and to give some personal experiences. Favus and ringworm, he said, were apparently local conditions, and when treated by iodine or other antiseptics the lesion disappeared. But farm-workers, having been once infected by cattle ringworm, were afterwards immune. Neisser and Plato experimented on these lines and attempted a treatment by means of a sterile filtrate of a crushed culture of the fungus prepared in the same way as "Old Tuberculin"; this they called "trichophytin." It was found that when this was injected into persons suffering from deep-seated ringworm marked local, systemic, and focal reactions followed, which, however, did not occur in persons not suffering from ringworm or in those in whom the condition was superficial. This showed that some tissue changes had occurred in sufferers from the condition when deep seated—in other words, they had become sensitised to the infecting agent. Experimentation was carried out on these lines afterwards by several workers on animals and man, and it was definitely shown that after inoculation with ringworm or favus the subject became less prone to later inoculation and eventually developed an immunity. Regarding serum, it was found that in marked cases of deep-seated ringworm a positive fixation reaction was obtained with a trichophytin antigen. Dr. Low experimented to see whether a skin-test could be obtained for diagnostic purposes in ringworm and favus of the scalp, using intracellular toxins and crushed fungus prepared by himself together with samples of trichophytin and favin prepared by Richardson and King. Results were as follows: 11 cases of small spore tinea capitis due to *Microsporon audoini* were tested; of these, four were negative, four doubtful and probably negative, and only three were positive. The tests were cutaneous. The practical value of these skin-tests was considered very doubtful. Regarding treatment, it had been found that, after injection of fungus extract, ringworm healed more quickly by stimulation of the skin to repel the disease. This was only true when the disease was deep seated. With ringworm of the scalp throughout the animal kingdom the young only were affected; in humans the disease died out spontaneously at the age of 14; treatment had been greatly shortened by means of X rays, but anything further to shorten treatment would be very acceptable. With this aim "microsporon" was injected, but the results were so disappointing that it was given up after treating five cases only. Concluding, Dr. Low stated that a deep infection with living fungus could produce changes in the blood and skin which were not true anaphylaxis but a form of sensitisation. In superficial fungus infection no sensitisation of the skin occurred, and that was the reason why ordinary ringworm of the scalp showed no tendency to spontaneous cure.

Exhibition of Cases and Specimens.

Dr. R. A. Fleming showed a case of *Congenital Heart Disease* in a girl aged 12, which presented difficulty in diagnosis. The patient had a definite presystolic thrill and great involvement of the right heart as evidenced by X ray and electrocardiogram. In spite of this she showed no cyanosis, polycythæmia, clubbing of the fingers, or other symptoms that might be expected.

Mr. J. W. Struthers showed a specimen of a *Mammary Tumour* weighing 11½ lb. The patient was a woman aged 56, who had only noticed it for two years. It was a simple tumour of a fibroid nature.

Dr. Chalmers Watson showed cases illustrating the ætiology and treatment of *Chronic Disease of the Nervous System*. Three patients were shown—a case of pseudo-tabes with weakness in the limbs and unsteadiness of gait, and two cases of disseminated sclerosis both with previous unsteadiness in walking and weakness of the legs. Dr. Watson made the patients walk and run to demonstrate improvement. A fourth case of disseminated sclerosis of five years' duration, when the patient had received previous treatment in the Royal Infirmary, was described. The object of the demonstration, Dr. Watson said, was not so much to emphasise the individual results as to draw attention to the principles. Treatment was directed to the correction of the various manifestations of autosepsis as revealed by physical examination and investigation of the urine and stools. This involved attention to diet, promotion of elimination, physical therapeutic measures, and, in certain cases, an attempt to increase the patient's resistance more directly by vaccine treatment. The details of treatment varied in the different cases, but the principles had uniform application.—Prof. Edwin Bramwell, called upon by the President, said that if Dr. Chalmers Watson's thesis were correct, it was a most important contribution, but that otherwise the title was unfortunate and misleading. A demonstration of this kind should take the form of a communication in order that details regarding the cases and other facts upon which the conclusions were based might be presented and discussed. Prof. Bramwell was of opinion that the demonstration was in itself unconvincing.—Dr. Watson, replying, said he merely stated facts and hoped to stimulate individual inquiry, bringing the study of nervous disease from the too specialised branch of neurology to the sphere of the general practitioner.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

A meeting of this section was held in the Royal College of Physicians, Dublin, on Nov. 14th.

Mr. R. C. B. Maunsell, the President, read a paper on two cases of

Carcinoma of the Rectum,

complicated by pregnancy and treated by excision. In the first patient, a woman aged 27, three months pregnant, the growth was removed by the perineal route after preliminary colostomy, and the patient was subsequently delivered of a full-time healthy child. In the second case the age of the woman was 38, and she was three months pregnant of her eleventh child. The combined perineal and abdominal route was used for the removal of the growth, and the pregnancy ended normally in the birth of a living child.

Mr. Seton Pringle said that on one occasion he had removed the rectum in a case of pregnancy. The patient had been pregnant over four months, and it would have been almost impossible to deal with the growth without first removing the uterus, and this he did. He was interested to hear that the President opened the colon before proceeding with the pelvic operation, though he personally thought that by doing this there would be danger of soiling, and that it was better to leave the opening of the upper segment till the conclusion of the abdominal section of the operation. He thought the only operation which could be called a radical operation was the combined abdominal and perineal. If the patient was young, and in good condition, he carried out the combined method, but in elderly people he did the two-stage perineal operation, as described by the President. He thought that in cases of rectal cancer, or cancer low down in the colon, the sphincters should never be preserved.

Mr. Henry Stokes said he had had no experience of cases of carcinoma of the rectum complicated with pregnancy, but some months ago he had done a two-stage operation on a fairly young woman for cancer of the rectum. She had one child, and 13 months after the operation she had another child. He believed that in such cases, after the operation had been done, if further pregnancies occurred there was no chance of sepsis.

Dr. Bethel Solomons said it was strange that in obstetrical text-books little space was devoted to the subject of cancer of the rectum as a complication of pregnancy. Usually there were a few lines stating that Cæsarean section was the treatment. The excellence of the results in the cases reported was a conclusive proof that extirpation should be practised when possible. In the second case, had radical operation been refused, Cæsarean section at term would have been the only method of treatment. The literature on the subject was very scanty. The only series of cases he could trace was in a paper in *Acta Gynaecologica Scandinavica*, 1922, i., pp. 445–458.

Mr. C. J. Macauley said that he had never had a case of cancer of the rectum complicated by pregnancy, but he agreed with the President in preferring rectus colostomy to iliac colostomy. Iliac colostomy would have gone too near the anterior superior spine. He did not think that the abdominal perineal operation should not be performed in people over 60, as he thought that very often in young people there was more tendency to widespread growth, and provided old people were in good condition he saw no reason why they should not stand the operation. A year and a half ago he had done an abdominal perineal operation on a man of 65, with successful results. A lot, of course, depended on the patient's physique, and the circumstances in every case were different. He personally never attempted to preserve the sphincters.

Mr. **Arthur Chance** said that he had recently had an opportunity of seeing ten cases of carcinoma of the rectum operated on at the Mayo Clinic. First a preliminary colostomy was done, and 14 days later a perineal incision was made. The first incision was oblique, and was made high up in the lateral wall of the abdomen. The muscles there were very deep, and therefore good adhesion was obtained. This opening was very convenient for the wearing of a colostomy belt. The incision was made large enough for the hand to be put in, and the liver and the pelvis were explored. The subsequent operation was done with the patient lying on the face, and it was done under trans-sacral anæsthesia. The patients never complained of pain, unless it was necessary to pull down the peritoneum.

Mr. **W. Pearson** said that he thought every case of excision of the rectum should be dealt with by preliminary colostomy. In cases of rectal cancer, he believed in perineal removal, unless there was special indication for the double operation. In cases of males the urethra was a danger. He thought that t was very difficult to keep these cases aseptic. When the combined operation was done, it could be done all in one stage or in two stages, and although it took a little longer he thought it was better to do t in one stage. The type of patient made a great deal of difference; in thin patients the operation was much easier to do than in very fat patients.

The **President** replied.

Mr. **Macauley** read a paper on a case of a Solid Tumour of the Mesentery, and Mr. **Stokes** described two cases illustrating the use of Murphy's button.

LIVERPOOL MEDICAL INSTITUTION.

At a meeting of this Institution on Nov. 20th Mr. **Bernard Chavasse** read a paper on

Arterio-sclerosis and the Fundus Oculi.

He said that the sphygmomanometer required to be supplemented by the ophthalmoscope, which, ince its electrification, was making a strong bid for more frequent use in general practice. He exhibited a series of autochrome lantern slides of paintings illustrating the main features of arterio-sclerosis as een under magnification in the living retinal vessels; uch as the well-known "copper wire" and "silver wire" arteries, "beading" of the streak of reflected ight on the arteries, "corkscrew" arteries and apillaries, opacification of the arterial wall, "pipe tem" sheathing of arteries, irregularity of the arterial umen, as well as later and final changes both in the vessels and in the fundus as a whole. Dealing with the ppearances at arterio-venous crossings, he said that he S-shaped bend produced in a vein by an overlying rterio-sclerotic artery—a sign which had been escribed as the most important of all the signs of etinal arterio-sclerosis—was one which needed qualication. He had observed it not infrequently in ealthy children. The necessary qualifications were he veiling of the vein by the ghostly arterial wall, he failure of the vein to shine darkly through the verlying arterial column, and a diminution in the alibre of the vein at the actual point of crossing. Given these qualifications, or at least the presence of ther signs of arterio-sclerosis in other parts of the undus, he agreed with Mr. Foster Moore that the sign was of great significance. He discussed its mechanical ausation and suggested that the earliest stage at which one could hope to recognise it was by the bsence of that optical illusion which caused the two alves of the more remote limb of any X-shaped figure o appear out of alignment. This feature, however, e felt bound to admit was not one on which much eliance could be placed without such special aids as he use of red-free light and special methods giving high magnifications. The appearance of "banking" of blood in a vein owing to its obstruction by an overlying sclerosed artery was one which he thought he had sometimes seen, but he had been unable to satisfy himself that the appearance was not in reality due to the "porpoise-like" course of a vein in and half out of retinal nerve-fibres which were assuming that cloudiness which was also a feature of arterio-sclerosis.

Dr. **W. Johnson** read a paper on

Borderline Cases in their Relation to General Medicine and Surgery.

He remarked on the light which recent psychological progress has thrown on the psychoneuroses. He reviewed the physical manifestations which were the result of emotional states, and pointed out that many patients with these symptoms were treated for medical or surgical conditions, without any attention being directed to the disordered emotional condition which was their real cause. Cases could be grouped into four types—abdominal, cardiac, cephalic, and (in women) pelvic—according to the physical symptoms which predominated. Surgical interference was to be avoided and had in some cases proved disastrous. The essential form of treatment lay in the application of the principles of mental hygiene.

Dr. **R. M. Manwaring-White** considered the subject one of greatest importance, particularly to the general practitioner. He considered that there were hereditary tendencies, that shock, emotion, fatigue were exciting causes, but he was surprised that there had been no mention of organic disease as the underlying causative factor. He instanced *B. coli* infection of the urine, infected teeth, and other septic infections. As regards treatment, he realised also the value of suggestion, but had experienced very little success from administration of suprarenal gland. In those cases with subnormal temperature and slow pulse he had frequently found benefit from thyroid administration.

Mr. **A. E. Davis** said that in his experience the great majority of neuroses and psychoneuroses had their origin in the emotion of fear. He was opposed to the Freudian theory of a universal sexual basis in these cases, and thought that dogmatic and unproven dicta, such as Freud's "in a normal vita sexualis no neurosis is possible," were positively detrimental to the proper study and advancement of psychological knowledge. Of the two primitive instincts, that of self-preservation was of greater moment than the sexual. Fear was the sine qua non of the instinct of self-preservation and was a biological necessity for the preservation of the race or species. By mental analysis carried into the child mind—the emotional and primitive mind in development as contrasted to the later developed and acquired powers of the conscious or reasoning mind—one was enabled to trace fear plus some exciting factor as the cause of psychoneuroses. This factor might be external, such as a mental trauma, or internal and toxic in character. True, the sexual obtruded frequently in the form of masturbation, but if this conflict was submitted to further analysis, the symptoms would be found due to the sense of shame and fear of harmful consequences, fear being predominant. Phobias and neurotic symptoms could be traced either to fear or to the irritability and hyperacuity of the senses due to exhaustion of nervous centres by long-continued stress and drain of nervous energy. They were not symptoms of disease but manifestations of tiredness and exhaustion, and could be remedied by mental rest in removing the doubt. He gave instances of emotion overpowering the evidences of the physical senses. The psychoneuroses were purely the expressions of emotional disturbances, and origins must be sought in, and treatment directed to, the emotional level, or so-called subconscious mind.

Royal Sanitary Institute.—The next Congress of the Institute and Health Exhibition will be held at Edinburgh from July 20th to 25th, 1925, by invitation of the Magistrates and City Council.

Reviews and Notices of Books.

THE HUMAN TESTIS AND ITS DISEASES.

By MAX THOREK, M.D., Surgeon-in-Chief, American Hospital, Chicago; President, International Congress of Comparative Pathology, Rome, 1924. London and Philadelphia: J. B. Lippincott Company. 1924. Pp. 548.

THE title on the cover of this book is somewhat misleading, because by far the greater part deals with the endocrinology of the gland, and the treatment of its aberrations of function. The first two chapters give a short summary of the anatomy and histology of the testes, which in no way differs from the ordinarily accepted teachings. The third chapter, of considerable length, is devoted to the physiology of testicular secretions, and is one of the most interesting parts of the book.

The author surveys the history of the various theories of testicular function, and reviews Berthold's early work on transplantation. His discussion centres chiefly on the function of the Leydig cells, and he reports the views of Ancel and Bouin, and Steinach's results on this subject. Voronoff's and Retterer's conclusions on the origin of the internal secretion are discussed at length, and finally he concludes with his own experiments and a statement of his own views.

Chapter IV. deals with the ordinary diseases of the testicle, and is disappointing. The whole subject, from anatomical anomalies through the infections down to the growths, occupies only 97 pages, of which 31 are just statistical tables. The acute and chronic inflammations are most cursorily dealt with, and the description of the growths is poor. It would appear that the author's main interest is in the errors of internal secretion, and that this chapter, though essential to his intention, was one to be completed as quickly as possible.

The remainder of the book is devoted to the endocrinology of the gland, and the subject is dealt with in great detail. There are apparently a great number of indications for sex-gland implantation, and the author concludes, from experimental and clinical findings, that the donors must be either human or of the higher apes. He employs two main methods of technique. In one the graft is implanted in the subperitoneal tissues beneath the rectus abdominis near the deep epigastric artery, and in the other the bed is the perirenal fat just below the lower pole of the kidney. The graft is prepared by removal from the donor intact in its tunica vaginalis, which is then removed and the tunica albuginea punctured in about ten places by the cautery in order to expose the tunica vasculosa. Dr. Thorek is reticent in his expressions as to the present position of gonadal implantation, and it seems probable that the graft does not live more than, at the outside, 12 months. Yet there appear grounds for belief that in certain cases of premature senility, loss of both testes, and one or two other conditions, marked improvement may occur in a sufficiently large percentage of cases to make the operation justifiable. With regard to organotherapy by mouth or by injection, he gives the gloomiest reports, and apparently there is little to be hoped for in that direction.

The book is admirably got up, with good type and excellent illustrations. Each chapter has its own bibliography, and at the end of the book an index of authors is given separate from the ordinary index. As a standard monograph upon the diseases of the testicle it will find no place, for the ordinary diseases are not well described, and there is little or no help for the practitioner with regard to diagnosis and treatment. But wherever research work on gonadal transplantation is being carried on, and for all those engaged in the practice of prolonging or retrieving an elderly man's sexual life, this monograph will be a refuge in times of difficulty.

A VADE-MECUM OF EMERGENCIES.

Manuel de petite chirurgie et de technique médical journalière. Third edition. By P. ADIN-DELTEIL, Professor of Clinical Medicine at the Faculty of Medicine of Algeria; and P. SLUBEYRAN, Professor attached to the Faculty of Medicine of Montpellier. Paris: Masson et Cie. Pp. 927. Fr.45.

THIS is a great deal more than a text-book of minor surgery; there are, in addition to the purely surgical matter, chapters on anæsthesia, massage and re-educative methods, the treatment of syncope and of various forms of poisoning, the clinical examination of medical and surgical cases, thermometry, sero-, hydro-, and balneo-therapy, disinfection and the management of contagious diseases, and, finally, on the performance of post-mortem examinations. Certain modifications have found their way into this third edition as the result of war experience, notably in the chapters on splints and surgical apparatus, and a new chapter by Mr. Bécart on blood transfusion has been added. The instructions given are so precise and so carefully laid down that, having once read them, it would hardly be possible to err in the performance of any of the many and varied operations with which the book deals. The volume might be very useful to resident officers in hospitals and to general practitioners as a book of reference in emergencies, medical as well as surgical.

MATERIA MEDICA AND PHARMACY.

Materia Medica, Pharmacy, Pharmacology, and Therapeutics. Eighteenth edition. By WILLIAM HALE-WHITE, K.B.E., M.D. London: J. and A. Churchill. 1924. Pp. 712. 10*s.* 6*d.*

POPULAR text-books are usually known by the name of the author rather than by their medical title, but we doubt if any is so much lost in its author's name as is the book in question. Everyone knows "Hale-White," few would be able to state its title. The words eighteenth edition cut the ground from under the critic, and at the same time make praise unnecessary. The strength of "Hale-White" is its well-balanced description of each drug; its weakness is the absence of that pharmacological generalisation about groups of drugs which eases the task of the learner and tells him what to learn. In this respect it differs from its newer rivals; they tend to teach the student theories and easy paths to knowledge, but to leave him stranded as to facts. "Hale-White" teaches him the facts but allows him to wander (perhaps to stumble) among them. Possibly the small print Materia Medica might be revised and purged. Students are apt to take fright and not to learn any of the constituents of drugs, or, on the other hand, to set out blindly to try to learn them all. Two small inaccuracies remain: the strength of the compound mercury ointment has escaped correction and pelletierine tannate is still indexed wrongly. The statement that "about 5 per cent. of chloroform to 95 per cent. of air is a good mixture" does not agree with modern experimental work, which shows that 2 per cent. is the maximum strength for safety.

We shall continue to prize "Hale-White."

Essentials of Pharmacy. With Questions and Answers. Second revised edition. By CLYDE M. SNOW, Ph.G., A.M., Professor of Pharmacy, University of Illinois School of Pharmacy. London: Henry Kimpton. 1923. Pp. 752. 28*s.*

IT is debatable whether such a big book as this should be written in the form of question and answer, but granted the principle of the "quiz" method we can commend this work as well done. We calculate that there are over 9000 questions and answers, a figure which shows to what an extreme this method of teaching has been carried. Some of the questions are on pure chemistry, others on pharmacy and dispensing, and others on the ethical and legal side of the pharmacist's art; to each of the questions the answer is added immediately. The book is well printed and well set up, facts which of themselves prevent the feeling of ennui usually created by the small type in which questions are added in many text-books. The book is written for the pharmacist; it goes far beyond what is expected of the medical student in the area of pharmaceutical work, but the contents are interesting to the medical man, and would be of greater interest if they were in compact form instead of a form suitable only for examinations. It is based on the United States Pharmacopœia and the National Formulary, and therefore contains terms and names of drugs which are unfamiliar to English ears.

BIOCHEMISTRY.

Microméthodes et semi-microméthodes. By Dr. DURUPT, ex-Chef de Laboratoire à la Faculté de Médecine. Paris: A. Poinat. 1924. Pp. 288. Fr.15.

THIS small volume contains descriptions of methods which have long since passed away, and are only of interest from an historical point of view. Practically all the methods of blood analysis are those devised by that great father of blood analysis, Ivor Bang. The book should be read by students just finishing a course of chemical pathology at the present time. They will then appreciate the thoroughness and amazing completeness of these old techniques, and be able to render to Bang the credit he deserves—a thing which most people omit to do. The book can only be regarded in the light of a memorial card.

GREAT MEDICAL MEN.

(1) *Lord Lister.* By CUTHBERT DUKES, M.D., D.P.H. (2) *William Harvey.* By R. B. HERVEY WYATT. London: Leonard Parsons. 1924. Pp. 186 and 214. 4*s.* 6*d.* each.

THESE two books form part of a series called the Roadmaker Series, the aim of which, says the publisher, "is to encourage interest in those British men and women whose lives and achievements have widened human knowledge, eased human ills, added to human resources and means of self-expression and strengthened the foundations of civilized society." Certainly, no two men have done more to widen human knowledge and ease human ills than Harvey and Lister. Much has, of course, been written about both, but the two little books before us contain a simple and vividly written account of researches which involved many years of labour before the undertakers thereof saw fruition. We notice that Dr. Dukes, in speaking of Lord Lister's father, Joseph Jackson Lister (1786–1869), (p. 25), says, in regard to his optical researches, "It was these discoveries that led to the production of the 'Achromatic Lens' and the perfection of the modern microscope." J. J. Lister certainly was the father of the modern microscope, but surely the credit of the achromatic lens belongs to Chester Moor Hall (1733) and to John Dollond, who, working independently, arrived at the same conclusions and published them about 1740. Hall had not made his discovery public. All the same Lister was the first to apply the principle to the microscope. Lord Lister's patient toil in perfecting his system is described with a simple clearness by Dr. Dukes which makes it comprehensible by any reader of ordinary intelligence.

Mr. Wyatt has a more difficult task than Dr. Dukes in explaining Harvey's discovery to lay readers, but we think that he has succeeded, and he leads up to Harvey's proof by giving a very clear account of Harvey's predecessors in the task. In one place he is led into looseness of expression—namely, on p. 31, where he says that "Hippocrates corrected Aristotle on the matter of the cardiac origin of the nerves. . . ." Seeing that Hippocrates is generally said to have been born B.C. 460 and Aristotle B.C. 384, it is hardly likely that the former would have the opportunity of correcting the latter, for he would be 96 when Aristotle was 20. Mr. Wyatt does not give the reference to Hippocrates, but he may be referring to some passage in a volume of the Hippocratic Corpus which was written after or during Aristotle's time. But the book as a whole is well done, and Mr. Wyatt supplies a most useful table of dates at the end.

JOURNALS.

BRITISH JOURNAL OF OPHTHALMOLOGY. October, 1924.—R. O'Connor: Diagnosis of Vertical Deviations of the Eyes. Want of balance of the muscles causing vertical movements in the two eyes is generally recognised as a cause of troublesome symptoms, capable of being corrected by the appropriate prescription of prisms. That such a want of balance can be latent so that it is not immediately apparent to the Maddox rod or other test but needs the prolonged occlusion of one eye to reveal it is not generally recognised. In 1920 F. W. Marlow, of Syracuse, New York State, put forward this view in the same journal, and now R. O'Connor, of San Francisco, writes in confirmation of it, citing 80 cases in which the test was applied for seven days, followed in most cases by the prescription of prisms which relieved the symptoms. In a minority of cases an advancement operation was undertaken.—Basil Lang contributes two short papers on technical points in the operative treatment of cataract, the first on a Modification of the Usual Method of Needling the Lens Capsule after Cataract Extraction, the second on a Modification of the Usual Method of Removing the Lens in the Extraction of Senile Cataract.—Microscopy of the living eye with the aid of the slit-lamp is a subject on which many workers are now engaged. Basil Graves contributes a paper on the subject, being the report in connexion with his Lang Research Scholarship. It deals with several technical details in connexion with the subject.—Besides the usual abstracts of articles from foreign journals, this number contains a letter from George Young and an editorial on the so-called medical treatment of cataract, both throwing cold water on the proposals which crop up from time to time to assist the absorption of striæ in the lens by means of eye-drops.

JOURNAL OF THE ROYAL ARMY MEDICAL CORPS.—In the issue for October Major M. B. H. Ritchie points out that the Army Medical Service, on which sudden and heavy demands are made in war ("the abnormal is the rule and the normal is the exception"), is yet not autonomous; the Director-General of Medical Services has no access, of right, to the Commander-in-Chief, the tactical disposition of medical units will be ordered by the Adjutant-General after consultation with the general staff, yet the transport required to effect the necessary movements does not belong to the R.A.M.C., but must be obtained from the Quartermaster-General. Personality alone can make such combined administration run smoothly, hence the medical officers should understand the thoughts of those who direct them, and some medical officers should be sent to study war at the Staff College. The old separation of soldiers into combatant and non-combatant is out of date; all are equally exposed to risk. The great need in future wars will be the conservation of man-power; who will here give greater help than the medical officer, who has already made it possible to wage war in countries in which, as in Palestine, disaster formerly overtook every invader? He urges that medical units should be considered as "troops," not as "services," and be made autonomous, so as to draw bright young doctors into the army, away from civil practice which now attracts them more. —Dr. George Stuart, Assistant Director of Health, Palestine, tells of typhus in Palestine in 1921, chiefly at Jaffa, clinically not easy to diagnose, but recognisable by the Weil-Felix reaction at some time during the first 12 days, in 1 in 80 or over, increasing on subsequent days.—Captain S. Smith, in virtue of his experiences at Secunderabad, advises that a severe or a suspicious sore-throat should be treated with antitoxin at once, diphtheria being commoner than usually thought, and antitoxin of most value if given early.—Captain T. O. Thompson gives an enthusiastic account of a day's fishing for "Bahmin" at Cannanore, with many good words for the Moplahs, who were recently in trouble.

SPANISH MEDICAL JOURNALS.

A BRIEF survey of the current issues of the Spanish medical periodicals which have reached us suffices to show that at all events in the larger centres of Spanish-American civilisation medicine in all its branches is well abreast of the times. These periodicals are: *La Semana Medica:* thirty-first year; Buenos Aires. *La Revista Sud Americana de Endocrinologia y Immunologia:* seventh year; monthly; Buenos Aires. *Revista de Medicina y Cirugia de la Habana:* twenty-ninth year; fortnightly. *Boletin de la Sociedad de Cirugia de Chile. Revista de Ciencias Medicas:* second year; monthly; Buenos Aires. *Estudios Medicos:* second year of new series; monthly; Murcia. *Archivos de las Enfermedadas del Corazon y de los Vasos:* Nos. I., II.; Barcelona.

Spain proper is only represented by two publications in this list—viz., *Estudios Medicos*, published at Murcia, and *Archivos de las Enfermedadas del Corazon y de los Vasos*, which appears to be the private venture of Dr. Duran Arrom, who is connected with the Institute of Practical Medicine in Barcelona, as Professor of the Pathology of the Circulation. In the latter the various problems of the heart are dealt with on the most modern lines, the papers being profusely illustrated by plates of cardiograms and sphygmographic tracings: the printing, plates, and paper are all excellent.

Estudios Medicos, which is in its second year but a revival of an older paper, is a journal of general medicine which draws its contributors from all over Spain, and has on its board representatives of all the chief centres of medical study. It is remarkable for its almost frivolously artistic appearance and the brilliant colouring of its advertising pages: merely as a specimen of typography it is really exceptional, but this does not prevent the articles contained in it from being of a solid character. Lengthy papers on the relation of medicine to criminology, and on the combined familial degenerations of the cord, and other neurological subjects, with illustrative cases, show a wide acquaintance with the work done in other countries. An illustrated article on the treatment of fractures of the femur by suspension and abduction is a satisfactory proof that the Spanish soldier is benefiting by the experience gained in the late war. Of the other contents, two long literary articles may be mentioned, one on the Don Juan type of man, and the other on the mental pathology of the works of Galdós, the novelist.

Of the South American journals, *La Semana Medica* is fairly comparable with the weekly medical journals of Europe or America. Many of the articles show keen clinical observation, and the reports of cases are, for the most part, remarkably complete. A typical number, August 7th, 1924, contains amongst others the following articles: (1) The Rôle of Phenolsulphophthalein in the Investigation of the Functions of the Kidney; (2) Cushing's Decompression Operation, with notes of two cases of fracture of the base so treated; (3) the Differential Tension in Aortic Insufficiency; (4) Two Cases of Traumatic Meningo-Encephalitis treated successfully with Electrargol and Antistreptococcic Serum; (5) Report of a Commission on the Prevalence and Prevention of Trachoma in the Argentine Republic. This report is followed by a much longer report on the whole subject by Dr. Barberini, one of the members of the Commission, to which the other members signify their assent. A sketch-map is given at the end showing roughly the prevalence and severity of the disease in the Argentine. The conclusions arrived at are, shortly, these: (1) That the disease is not autochthonous but has been introduced by the alien immigrants, large numbers of whom come from countries known to be seriously affected—e.g., Italy, Spain, and Russia, and is now widely diffused throughout the Argentine, especially the districts of Tucuman, Santa Fé, and San Juan. (2) That compulsory notification is necessary and a more rigid inspection of immigrants. The establishment of centres in the worst regions under the control of specialists is recommended where every means for the prophylaxis and cure of the disease may be adopted. (3) That the coöperation of the central and local authorities is necessary effectively to combat the disease and enforce the regulations which should be made by fresh legislation, the old law having proved ineffectual. (4) All workshops and factories should be inspected periodically and the personnel affected treated at the expense of the owners. (5) To carry out these measures requires besides a trained and disciplined personnel, persistency, method, and adequate financial arrangements.

As an indication of the progressive character of obstetric medicine in Buenos Aires, an article should be mentioned from the *Semana Medica*, of July 3rd, on Fœtal Cardiotelephony and Phono-cardiography. A question of priority between Buenos Aires and Breslau. The Spanish specialists appear on the evidence to make good their claim of having anticipated their German colleagues by some six months in what to the non-specialist appears a somewhat remarkable achievement. The illustrations in this journal, speaking generally, are not on a par with the rest of it, and leave much to be desired in the way of clearness—e.g., the cardiograms are illegible in places.

La Revista Sud Americana de Endocrinologia Immunologia y Quimioterapia is what its title implies, and appears to be well up to date. An article on the treatment of chronic trypanosomiasis and "mal de Caderas" (an equine disease) by "Bayer 205" is, perhaps, the most important in the numbers to hand. *Revista de Ciencias Medicas* deals less with clinical matters and more with general medical problems; it devotes a good deal of space to contemporary literature. The most important article is one by Dr. G. Pittaluga, on the first meeting of the Committee of Hygiene of the League of Nations, which he concludes by expressing his conviction of the value of the work done. The Bulletin of the Society of Surgery in Chile shows that the Society was founded in 1922, holding its first meeting in October, and has carried on an active existence since. It is mainly a record of the clinical work and experience of the various members. As such, it shows that the surgeons of Santiago are fully alive to the latest developments of modern surgery. In proof of this, articles may be instanced on Periarterial Sympathectomy in Varicose Ulcer of the Leg and Perforating Ulcer; two cases of Acute Pancreatitis with recovery after operation; Splenectomy in Familial Jaundice with a successful case.

Revista de Medicina y Cirugia de Habana is a monthly publication on general lines. One article is of great interest: it gives the result of operation for congenital cataract in a man of 29 with valuable details about his psychological condition when he recovered sight—a remarkable account. An article on Basal Metabolism shows a full appreciation of its importance in modern medicine.

With regard to Spanish medicine, it is difficult to fix on any standard of comparison as so little has been known of it in the past. With the exception of Ramon y Cajal, the great physiologist, it is doubtful whether any Spanish name has been heard of by a dozen Englishmen in the last 30 years. Judging, for what it is worth, from the International Congress held in Madrid in 1905, it may be said that the last 19 years have shown marked progress, and a laudable desire to keep up with modern thought. The expanding communities of Spanish South America have, no doubt, always had a higher standard in their great centres, and have probably felt to some extent the influence of the United States, where medical progress has been very rapid in the last 20 years. The difficulties of language, though not really great for anyone familiar with Latin or its congeners, must always be a bar to any widespread acquaintance with Spanish medical literature; nor can it yet be said that it is worth while for anyone to learn Spanish simply in order to study that literature. Nevertheless, there are, in the periodicals under discussion, contributions which would be interesting and valuable to students of almost any branch of medicine or surgery, and these are likely to increase rather than diminish in the future. It must be remembered that there are many other Spanish journals, though those mentioned probably represent the most progressive centres, excepting Madrid, the journals of which are not amongst the number.

Though the question is commercial rather than medical, it is impossible to glance through these journals and not be struck by the fact that the advertising pages show an entire absence of any English names, whilst American, German, and French firms are largely to the fore, especially the last. The same difficulties of language, added to the fact that we have not got the metric system, probably militate against a commercial, as they do against a medical, liaison, but in the former case it might reasonably be supposed that there are substantial grounds for overcoming them with such a large market open!

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

FURTHER SITTINGS.

(*Continued from p. 1020.*)

THE Commission[1] resumed its sittings on Tuesday, Nov. 18th, this time at 1, Whitehall-gardens, with Mr. H. P. Macmillan, K.C., in the chair.

EVIDENCE OF MEDICAL SUPERINTENDENTS OF MENTAL HOSPITALS.

The first witness was Dr. J. Francis Dixon, medical superintendent, City Mental Hospital, Humberstone, Leicestershire. He said the institution accommodated 1000 female and 350 male patients. The Chairman, remarking that the Commission was interested in the smooth working of the Lunacy Acts, asked if Dr. Dixon had any suggestions for the simplification or improvement of the code under which he worked. The witness replied that, in general, if one interpreted some of the legal enactments strictly according to the letter of the law, innumerable difficulties could be raised; but if one went just behind the letter to get at the spirit of the requirement, then it would be found that many difficulties were able to be overcome. He instanced the Continuation Order and admitted that he felt some embarrassment in signing it in cases of convalescence or recurrent cases which might have lucid intervals, lasting perhaps as long as a year. It was difficult to give a certificate of continued insanity in such cases. Nevertheless, he had no doubt as to the desirability of the continued detention of the patient, for a time at least. He frequently took advantage of the power he had of allowing patients out on trial for 48 hours at a time, especially in cases of convalescence, in order to accustom them to the normal mode of living.

The Chairman, referring to the suggestion that in the incipient stage it might be desirable to avoid the stigma of certification, asked if it would be advisable to have a continuing certificate in a modified form. He did not like forms which compelled people to state things they did not believe, and it seemed that in some cases there was doubt as to whether a patient should be certified as of unsound mind.

Dr. Dixon agreed that the form now in existence might be modified. Was it necessary to say that the patient was still of unsound mind? It seemed to him that it would be better to say "the patient is now convalescent but still requires further treatment, to which he consents."

The Chairman said it would be interesting to know whether during his long experience Dr. Dixon had encountered cases in which he, on examination of the patient, admitted he was satisfied that it was not a proper case for detention. To this Dr. Dixon replied that he had encountered cases in which he had been unable to confirm the statements made in the certificate, but that was a somewhat delicate matter, inasmuch as although a patient might have had all the qualities that had been assigned to him, yet at the particular time he examined him they might be absent. The patient might be one who was unaccountable for his actions over a short period of time. In such a case if he had to say in the first report that such a patient was, in his opinion, insane he would experience a considerable amount of difficulty. The witness agreed with the Chairman that in the matter of discharge the medical superintendent's view of the case should be the predominant element. Asked if he thought there should be facilities for independent investigation of a case at the instance of the patient or relatives, Dr. Dixon said he thought that in all probability such facilities would be most undesirable, for the reason that those who complained most about asylums were the insane.

Safeguards for Visiting Patients.

Replying to a question as to whether sufficient safeguards were provided for visiting patients and for access to them by independent medical men, Dr. Dixon said, speaking from his own experience, that there was a tendency rather to object to publicity mainly owing to the feeling that the whole thing was more or less confidential. He was, however, in favour of anything which would help to humanise the patients and produce normality, as far as it was possible to produce it, and the more the patients came into contact with the right type of people from the outside world, the better for them. He agreed that the effect of being continually in the society of those suffering from the same malady was detrimental to recovery. There were facilities for the mental treatment of patients up to a certain point, and in some cases definitely curative treatment was undertaken, such as the treatment of general paralysis by inoculation with the malaria parasite. Patients in his institution were, on admission, classified, not according to their disease, but on the amount of liberty that could be given them. Proper classification was most important and there should be adequate accommodation for that purpose. He deprecated the present machinery under which a patient had to go before a magistrate prior to certification. It seemed to him to create in the mind of the patient a feeling that he had committed some wrong and was therefore in the hands of the law, rather than entering a hospital to be treated for a disease.

The Nursing Staff.

There was now, he said, some improvement in regard to the nursing staff of mental hospitals, but he thought the senior members did not receive sufficient remuneration, while the juniors in training received, in proportion, too much. It was his view that mental nursing called for a higher kind of work and greater personal qualities than did general nursing, and if the career was to attract those with the necessary qualities and education, there must be proper remuneration and some prospects. He thought it very desirable that persons suffering from incipient insanity should be able to obtain treatment without necessarily being certified. Still, he thought that in the public mind the stigma attaching to certification was due to a misconception, probably traceable to traditions associated with the malady, and that with general enlightenment such would diminish, though he did not think it would entirely disappear. The Chairman asked whether this end would not be helped by having the patients treated at first in homes or institutions which were more hospital than asylum, where they could remain for a time before being stamped as insane. The witness replied that if certification were the bugbear the matter might be carried further and have nobody certified, simply have the temporary order continually renewed. Certification was a protection to those who were dealing with the patient requiring, or who might require, restraint. At the end of last year the number of patients in his institution was 842, and during that year there were 189 admissions, of which 39 were readmissions. The recovery-rate was 37·12 per cent. of admissions. If two certificates for the rate-aided patient were favoured, the second should be signed by a specially qualified medical man, or one appointed for that purpose.

---

[1] The personnel of the Commission is as follows: The Right Hon. H. P. Macmillan, K.C., standing counsel to the Convention of Royal Burghs, Scotland (Chairman); Earl Russell; Lord Eustace Percy, M.P.; Sir Thomas Hutchison, Bt., Director of the Commercial Bank of Scotland, and Lord Provost of Edinburgh, 1921-23; Sir Humphry Rolleston, Bt., K.C.B., M.D., President of the Royal College of Physicians of London; Sir Ernest Hiley, K.B.E., at one time town clerk of Birmingham, and formerly M.P. for the Duddeston Division of that city; Sir David Drummond, C.B.E., M.D., Pro-Vice-Chancellor of the University of Durham, and formerly President of the British Medical Association; Mr. W. A. Jowitt, K.C., M.P.; Mr. F. D. MacKinnon, K.C.; Mr. H. Snell, M.P., a member of the executive committee of the Fabian Society, and formerly a lecturer for that society; Mrs. C. J. Matthew; and Miss Madeline J. Symons, of the Women's Section of the National Union of General Workers; with Mr. P. Barter, of the Ministry of Health, as secretary. All communications regarding the Commission should be addressed to The Secretary, Royal Commission on Lunacy and Mental Disorder, Ministry of Health, Whitehall, S.W. 1.

Replying to Earl Russell's suggestion that the patient instead of being described as a certified lunatic should be known as " a mental case under compulsory treatment," witness agreed it would be well to start afresh and use some other term than "lunatic."

Mental Recovery-rate.

Dr. O. G. Connell (superintendent, Norfolk Mental Hospital, Thorpe) was next examined. He said the principle of the reception order was sound, but the same procedure should be adopted for the rate-aided as for the private patient, especially in requiring two medical certificates. He said the recovery-rate in his institution in 1923 was 35 per cent. of admissions, and this year, so far, it had been 45 per cent. In some institutions the rate reached 70 per cent. This year he had received 197 patients, only seven of them being readmissions. Cases likely to benefit by treatment should not be certified, but should be received as voluntary cases. Some people who had been in the institution were quite ready to come back if there were any return of their malady. One woman in such pass pretended to commit suicide so as to cause her admission again. The witness admitted that if voluntary patients were admitted to mental hospitals the latter should have some power of detention; it would suffice if 72 hours' notice of intention to leave were given, to prevent a patient discharging himself if he had a breakdown, for that time would enable communication to be established with his relatives, or guardian, or the relieving officer. The chief difficulty in the matter of after-care was people's shyness to recommend for employment anyone who had been an inmate of an ayslum. If the Mental After-care Association were sufficiently encouraged many mental hospitals would be glad to send out patients under that body's supervision. In his institution in the last three years only two cases of ill-treatment of patients had occurred, both trivial, but in each case the defaulting attendant was dismissed, as the strictest discipline was essential.

Answering Sir David Drummond, Dr. Connell said he thought the study of insanity should receive a better place in the medical student's curriculum, though admittedly the doctor's practice provided him with some experience on the subject.

The Lunacy Act a Protection to the Patient.

The Commission continued its sittings on Wednesday, when Dr. H. Devine (medical superintendent, Borough Mental Hospital, Portsmouth) was the first witness. The Lunacy Act he regarded as an almost perfect instrument of detention, and he did not doubt it protected the patient. Its chief defect from the psychiatrist's standpoint was that it insisted too much that every certifiable patient should be certified. He had only encountered one case which, at the end of a week, he could declare was not insane, and he was an evident malingerer. Still, he thought Poor-law cases, as well as private ones, should be certified by two medical men; it would avert possible public criticism on the ground of discrimination against the pauper patient. The hesitation of Poor-law authorities to go as far as certification might prejudice the patient's recovery by delaying expert treatment. He favoured such patients being brought direct to the mental hospital and being lodged in a detached part of it without certification. He proceeded to detail the procedure when patients were admitted. A maniacal case would be segregated. He was in favour of an asylum constructed as a series of villas, rather than a barrack-like structure. He said that the mental hospital which served a particular town should be in the town itself, and it was desirable that it be recognised as the centre for the treatment of all the mental illnesses of the community; especially was this so in view of the possibility of maintaining social relationships with the outside community; the more social contact the patients could have the better. In answer to the Chairman, he said he did not think every mental hospital should be expected to be a centre for research; smaller institutions would have the benefit of the equipment and the results of the more elaborate. He agreed that certification was a slur on the reputation of the certified, though it should not be. He had known even the children of a victim of puerperal insanity brought up under the idea that they were mentally abnormal. He considered that the Scottish system of simple notification, without publicity or stigma, worked well. If, however, those under this scheme objected to or resented treatment he would have them fully certified. He would not like a hostile voluntary boarder under his care unless, when that occurred, he could be certified. He said that if the Mental Treatment Bill was to be of value it must give power of detention on simple notification of people who were insane but whom it was undesirable to certify, because their condition was hopeful in regard to recovery. Establishments which took in and cared for uncertified cases should be under the control of some central or local authority.

The Chairman reminded the witness that the medical man naturally concentrated on the welfare of the patient, but the public point of view was concerned with the prevention of possible abuses.

General Hospitals and Mental Cases.

Dr. Devine replied that some asked to be taken into the asylum because they did not want to carry out their tendency to commit suicide. He thought there was good ground for the dread of the stigma of insanity, and all possible should be done to delete or minimise it. Still, he did not believe in reserving asylums for only chronic cases. He strongly favoured the idea of dealing with mental cases in general hospitals, especially those to which a teaching school was attached. And it would be good for the profession, as at present the average medical student had the most grotesque ideas on insanity.

The Chairman said the great obstacle was the long duration of mental illness, making it necessary to make provision for a long residence.

Dr. Devine said he agreed, but if this method could be employed, many cases would not reach the asylum stage. It had been successfully carried out in Edinburgh, where alcoholic psychosis, operation psychoses, and many forms of depression, cases brought in by the police, were treated in general wards. In reply to Sir Humphry Rolleston, he said he thought any institution associated with the detention of persons of unsound mind would be liable eventually to have the same unpleasant associations in the mind of the public as asylums now had. But there was hope that the gradual enlightenment of the public on these questions would largely mitigate that feeling. Because of this prejudice, the word "nerves" was often applied to a slight degree of mind disturbance. The Maudsley Hospital would prove a means of educating the public in these matters. He fully agreed that the seriousness of mental disease was its effect on the responsibility of the individual. He thought the element of compulsion in relation to asylums was greatly exaggerated; many of the patients were thankful to get the treatment the asylum afforded. Bearing on the question of the possibility of admitting cases without certification, he said that of the last 50 female admissions 9 were willing cases, 33 were indifferent and confused, and 8 were unwilling and considered themselves the subjects of persecution; they were delusional. Answering a further question, Dr. Devine said he hoped the function of the relieving officer in this regard would be done away with; he advocated a complete dissociation of the subject from the Poor-law. A panel doctor should recommend a case for admission to the public mental hospital. In the case of notification he would have a kind of extended urgency order, thus avoiding the formality associated with the attendance of a magistrate. These patients could be transferred to a nursing home, where they could be under the supervision of some authority. In a general hospital a separate block could be set aside for them, and in a small town one or two villas could be either set apart or built for the same purpose.

He next answered a number of questions on the practice of

Sending Patients Out on Trial,

remarking that even if a patient did not come back according to promise, he was still regarded as in the custody of the asylum and steps were at once taken to recover him and have him cared for meanwhile. He did not think there was any risk of patients being detained in an asylum beyond the time at which they recovered their mental health. He did not think it was necessary to ask justices to share the responsibility in this matter. Asked as to the staff, he said it was sometimes difficult to get the right kind of people as candidates for probation, and the staff, other than the trained nurses, were a fluctuating asylum population. He agreed with Lord Russell that if voluntary treatment was not found to be quite sufficient in a particular case it would be a very good plan to enact the original steps of notification and then for the justice to suspend his order for a period longer than 14 days, for then, if anything went wrong, everything would be in order for actual certification. He declared, in answer to Mr. Snell, M.P., that some cases could not be correctly diagnosed at the first interview, and among the most difficult were the most dangerous, such as paranoiacs and those with delusions of persecution. He had three medical officers in his institution with 800 patients.

Sir Humphry Rolleston asked Dr. Devine whether he thought the Act should be modified in any way so as to protect the doctor from vexatious and unjustifiable actions while still preserving the full protection of the patient.

Dr. Devine thought such might be effected, because the doctor merely took the part of witness in the process of certification. The reluctance of doctors to certify was very great; in fact, some would not certify. He was not prepared to recommend what form such amendment should take. Asked by Sir Humphry Rolleston whether it would not be well that the second certificate should be signed by the medical officer of the institution to which it was intended the patient should go, the witness agreed. Answering further questions, he said he favoured having a clinic in association with the mental hospital, though some criticised such a proposal. His recovery-rate last year was 25 per cent., but he thought the figure would be less for this year; much depended on the kind of cases received.

Advantages of Early Treatment.

Dr. H. Wolseley-Lewis (medical superintendent, Kent County Mental Hospital, Maidstone) was next examined. He said he was present while Dr. Devine gave his evidence, and with it he largely agreed. But in speaking of mental clinics, Dr. Devine rather inferred that they should be clearing-houses for certified cases. His own notion of clinics, especially as applied to the county, was that they should be as near the homes as possible, and that they should be entirely voluntary, and free from the fear of certification. It was of great importance that cases of mental trouble should come into the range of expert treatment at quite an early stage. With that in view the public should be encouraged to resort to them voluntarily, and it would be a pity to have any formal powers of detention of any kind. He agreed it would be unfortunate to have a case sent back to home circumstances at a crisis in the illness; in such an event, the friends could be asked to remove the patient, or the case could be reported to some authority with a request to deal with it. He said that 60 per cent. of all patients admitted to his institution during 20 years were known to have been ill a month or more before admission, and that seemed to constitute a serious indictment of the present system. He meant that that large proportion had been allowed to be without expert treatment until they were bad enough to be certified; in other words, until the general practitioner had been forced to that step. The clinic should have an in-patient as well as an out-patient section, and under such an arrangement he thought a considerable number of the 60 per cent. of admissions would not have been certified. Most recurrent cases were fully aware that they were not well, and would seek treatment long before they reached a certifiable stage. At present they had nowhere to go, except to the general practitioner, who, as a rule, was not very expert in treating such conditions. He did not advocate these clinics being associated directly with the public asylums, but he thought it would be wise for the whole mental health of the community to be under one central authority, and a great benefit if it had no association with the Poor-law at all. Many large country houses might be found available for use as clinics; it would not always be necessary to build them. For puerperal mania, and such conditions, he would like to see operative some powers of temporary detention, to be exercised at the mental hospital, not at the clinic. He would like to see, in county mental hospitals, a large number of voluntary patients who were remaining as voluntary boarders. They would be certifiable people, but not necessarily certified, and he would like all such places to be open to inspection by a Government department and by the local authority too. He would like to make the asylum more popular by removing from it in the public mind the conception of hopelessness; even as it was at present, these institutions were less "suspect" than in former times. Voluntary boarders would have to have their condition periodically reported to the Board of Control, to show they continued to be fit subjects for this method of treatment. Every legal precaution should be taken in the case of those certified, and he did not think the whole of the onus should be put on the medical man, and certainly not upon the medical superintendent of the institution.

Dr. Wolseley-Lewis said that at the present time, out of his 1800 patients, 300 of the women and 200 of the men were in open-door wards, and therefore could escape if they wished to. A considerable number were allowed out on parole. Many had sufficient insight to realise that they were better off inside the asylum than they would be outside it at present. In the case of certified patients, he thought discharge should be granted in the presence of a legal authority.

Pauperised Patients.

Answering Mr. Micklem, K.C., the witness said it seemed to him to be a great hardship that a large number of patients who came to the mental hospital should be pauperised in order to get treatment, as they were not paupers. Clinics should be established by the municipal authorities or by the county. He admitted that he had found relieving officers' work in connexion with mental hospitals had been very well done; but there should be better facilities for taking patients from their homes to the mental hospital, such as by motor ambulances, and a trained staff should accompany those vehicles. At present many patients were induced to come under false pretences; were told often that they were being taken to a convalescent home. He thought certain justices of the peace should make it their business to know something about this aspect of administration.

Answering Mr. Snell, M.P., Dr. Wolseley-Lewis said it was fair to assume that of the 60 per cent. of cases who had been mentally ill a month before admission to the asylum, a fair proportion would not have been certified if early treatment had been given them. He could not commit himself, off-hand, as to the proportion, but it was quite appreciable. Asked as to the training required of the staff, he said the whole matter was dealt with in the nursing report of the Board of Control, of which committee he was a member. It was recognised that for a number of years there would still be "attendants," as distinguished from male nurses. The former were excellent up to a point, but were not highly-trained nurses.

Asked by the Chairman whether he approved, in a general way, of the recommendations of the English Lunacy Legislation Committee of the Medico-Psychological Association, 1918, he replied in the affirmative.

The L.C.C. and Lunacy Administration.

The next witness was Mr. H. F. Keene, O.B.E., Chief Officer of the London Mental Hospitals Department of the London County Council, who set out in detail the regulations and provisions under which the County Council came into relation with lunacy administration. He said there were 28 boroughs having their own special authority under the Lunacy Act. In the case of the City of London, the authority was the Common Council. The local authority must provide the necessary accommodation for pauper mental patients, and it had power to provide that for private patients also. The powers were exercised through a visiting committee. He set out in detail the duties of visiting committees.

The meeting then adjourned to Tuesday, Dec. 2nd, and Wednesday, the 3rd, at 10.30 A.M. each day.

PORTABLE WIRELESS FOR CONVALESCENT PATIENTS.

No one will dispute that broadcasting is likely to prove a comfort to the sick and a help towards convalescence, but there are certain practical difficulties in the instalment of wireless apparatus which hinder its extended use. For instance, the local programme may not be appropriate to the patient's condition, and he may not have a receiver powerful enough to enable him to select from the various broadcasting and relay stations up and down the country, although a good selection of suitable items can generally be obtained from the programme of any one station for three or four days in the week. Again, the conditions in a private house are not as favourable as those in hospital where wireless is now being "laid on" almost as a matter of routine. The ordinary apparatus requires to be connected both to earth and to an aerial, neither of which can be improvised at a moment's notice. A self-contained wireless receiver which could be carried from room to room and used with either head-phone or loud speaker would be very welcome where sickness or convalescence is concerned. We have made some little inquiry as to whether such apparatus is to be bought at a moderate price, or hired where the need is only temporary.

Messrs. REES MACE AND CO. (50, Pall Mall, London, S.W. 1) supply a portable wireless set contained in a wooden case about 16 in. by 16 in. by 4 in., and weighing 30 lb. Placed upon a table during broadcasting hours, it is only necessary to attach a loud speaker or head-phones, to open the door of the case, and to turn a control knob when the sound comes through with perfect clearness provided the distance from the broadcasting station is not too great; we have tested it ourselves with satisfaction at a distance of eight miles, and with proper adjustment we understand that it can be used at twice the distance or more. Naturally, with an aerial the distance could be greatly increased. Something, too, depends on the loud speaker, for with a little box known as the "Celestion," about 12 in. by 5 in., a clarity of tone was realised closely simulating the actual presence in the room of the entertainers. Much ingenuity is apparent in the construction of the receiver. The batteries, which inevitably add substantially to the weight of the instrument, require attention not more than once in six months. A fuse makes it impossible to burn out the valves by careless handling, while the cushion placed between the valves and their socket minimises the risk of accidental jars. The whole adjustment can be learned by anyone in a minute or two. Three different forms of the Rees-Mace All-in Wireless Set are supplied. The one-valve set, for use with head-phones only, costs £12, and is let out on hire at 17*s.* 6*d.* per week. The two-valve set, price £19, or 21*s.* a week, has a greater volume and clearness of tone and takes a loud speaker. The three-valve, price £22, or 25*s.* a week, makes the loud speaker available at an increased range.

Messrs. SIEMENS BROTHERS AND CO., LTD. (Woolwich, London, S.E. 18), supply an instrument at £39 (less 10 per cent. discount to hospitals which undertake not to re-sell it), measuring about 16 in. by 11 in. by 10 in., and weighing 28 lb., which contains a small internal frame aerial which can be turned to any direction, thus assisting to prevent interference, and with a range of 15 miles. The dry cells it contains last from three to four months. There are three dull emitter valves, of which one, used as a note magnifier, can be switched on and off as required. By adding plug-in coils the continental stations are caught. The apparatus is simple to regulate and there is little risk of damage from an inexperienced person.

THE WESTERN ELECTRIC COMPANY, LTD. (Connaught House, Aldwych, London, W.C. 2), supplies many interesting sets which can be used with a frame aerial, and one without, price £17 17*s.* 6*d.* (10 per cent. discount to hospitals). A suitable amplifier is supplied at £5.

THE METRO-VICK SUPPLIES LIMITED (4, Central Buildings, London, S.W. 1) supply five-valve sets ranging in price from £32 to £74, which give satisfactory results without outside aerial.

THE CITY ACCUMULATOR COMPANY (10, Rangoon-street, London, E.C. 3) is showing at the "White City" Wireless Exhibition a portable receiver for which many advantages are claimed. Weighing only 16 lb., measuring 14 in. by 12 in. by 8 in., and with a range of 20 to 25 miles using a loud speaker, this instrument is produced at a cost of £20 plus Marconi royalties of 50*s.* Components are supplied which would enable an invalid capable of doing light constructional work to assemble his own receiving instrument on a small scale. A specimen was shown of such work actually carried out by a patient while lying in bed in the Special Surgical Hospital at Shepherd's Bush; this was an excellent crystal receiver of the two-circuit variety, the wiring being particularly neat.

Many of the firms showing at the Exhibition supply components for this kind of work, one of the number being the IGRANIC ELECTRIC CO., LTD. (149, Queen Victoria-street, E.C. 4), whose radio-devices are well known among amateurs. Messrs. W. BULLEN (38, Holywell-lane, E.C. 2) devoted a whole stand to loud speakers in great variety. Another firm with devices which will appeal to the invalid constructor is Messrs. PETTIGREW AND MERRIMAN, LTD. (122, 124, Tooley-street, S.E. 1).

The Marconiphone Company Limited at the moment are unable to provide facilities for convalescent patients who may desire to listen to broadcasting. In the early days of the industry they did loan, and in many cases presented, sets to various hospitals and similar institutions, as well as giving demonstrations in Marconi House. But for some time past they have been reluctantly compelled to discontinue the practice of loans.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 29, 1924.

THE GENERAL MEDICAL COUNCIL.

The 120th session of the General Medical Council, which was opened on Tuesday last, was presided over by Sir Donald MacAlister, whose presidential address will be found in another column. There is much in the programme thus outlined, and in the activities briefly alluded to, of widespread interest; taken as a whole the record shows the Council to have a steadily increasing range of duties and to be undertaking responsibilities of the most important character. The position as regards the Irish Free State and the jurisdiction of the General Medical Council is, for example, a delicate one, and the Council are rightly considering the matter in camera. It may be difficult to find the exact course which will satisfy the inclination of all, but the situation ought to be made definite without further delay. The relations of this country and Italy on the matter of reciprocity in practice are in an anomalous phase, for privileges at the present moment are being withdrawn from British practitioners in Italy which are extended to Italian practitioners in this country. Such matters require statesman-like adjustment, and the same may be said of the course to be adopted in respect of the degrees granted by certain Indian universities. For example, the recognition of the Calcutta University degrees as conferring a title to registration and qualification for practice in the United Kingdom is in risk of being withdrawn unless some argument stimulating that University to the necessary action can be speedily found.

The time of the Council is being occupied, as usual in the November session, mainly with cases of discipline where the Penal Cases Committee has found that evidence calling for inquiry and for answer on the part of a practitioner is forthcoming. In view of the statements recently made in several quarters that practitioners of high standing have disregarded the warnings of the Council in respect to advertisement, the President's reminder is timely that the Council cannot institute an inquiry without the submission of substantial prima facie evidence. We have on several occasions recently pointed out to correspondents that there was no reason to suppose that certain advertisements complained of had directly or indirectly emanated from the practitioner concerned, and more than once we have been in possession of a disclaimer to that effect before the complaint had been received. The general impression of our readers, however, is that considerable laxity now prevails, so that a further indication of awareness in the body of the General Medical Council would be timely.

MINERS' PHTHISIS ON THE RAND.

The report[1] for 1923 of the Miners' Phthisis Medical Bureau of the Union of South Africa is packed with interesting information. The bureau is concerned, under an Act of Parliament, with the investigation of industrial pulmonary diseases on the Rand, and the report records the clinical, pathological, and statistical operations which have been carried out during the year. It is not easy reading. A considerable proportion of the 40 pages of which it is composed is occupied by tables and schedules of clinical and pathological examinations, of the incidence and distribution of silicosis and tuberculosis, of subsequent histories, and so forth. Interspersed are explanatory paragraphs, but these are so condensed as to add but little to the enlightenment of the non-technical reader. A more detailed discussion of the data supplied and of their significance—a general survey, in fact—would indeed add greatly to the value of this publication, the importance of which may not be obvious to those who have not studied carefully the previous reports.

Elaborate methods of examination and careful case records have resulted in the attainment of a high degree of excellence in diagnosis, but at the same time the possibility of errors in the clinical data can scarcely be negligible. Is it possible to differentiate invariably and with certainty between simple tuberculosis, tuberculosis with silicosis, and simple silicosis in its forms ante-primary, primary, and secondary? Inasmuch as the pathology of miners' phthisis is still uncertain, this is a matter of considerable importance in the elucidation of the disease. It would be of great interest, for example, to know whether there is a reasonable possibility of the silicotic person becoming physically normal again if he relinquishes mining for some other occupation. The report suggests that change of environment has a relatively slight effect upon the subsequent history of the majority of cases, because "the great majority of cases of simple silicosis owe their earliest detectable development to the presence of an occult tuberculous element," and goes on to say that "the miner with simple silicosis is specially liable to become a source of tuberculous infection to others." The latter statement may mean that a tuberculous infection superimposed on a state of silicosis tends to be unusually acute and to give rise to the excretion of larger numbers of bacilli than does a simple infection. But put together these quotations suggest that the diagnosis is by no means an easy matter. This opinion is strengthened by the statement that simple silicosis is diagnosable pathologically by the development of areas of more than microscopic size from the minute lesions which are present normally in dwellers in the Transvaal. "This change appears to be the result, in at least many instances, of a peculiar form of tuberculous infection generalised throughout the lung; although, unless other and more orthodox indications of tuberculosis subsequently appear, the condition is still considered to be one of simple silicosis." The clinical diagnosis of simple silicosis must rest on pathological controls, and it is reasonable to limit the pathological diagnosis of silicosis to those cases in which the condition can be recognised in the lungs by unaided vision and touch, since the majority of the inhabitants of the Rand apparently show a certain number of microscopic lesions. But, on the other hand, a hardly justifiable latitude appears to be allowed to the radiologist, for "as a result of continuous improvement in apparatus and procedure, however, it can now be alleged that if a technically satisfactory radiograph, taken within a few months of death, has not disclosed the earliest signs of simple silicosis, these will not be discovered by the pathologist. It has indeed been remarked, on more than one occasion of late, that the radiographic evidence appeared to be more pronounced than that afforded by subsequent post-mortem investigation."

---

[1] Report upon the Work of the Miners' Phthisis Medical Bureau for the Twelve Months ending July 31st, 1923. Cape Town: Cape Times, Ltd., Government Printers. 1924. 3s.

From the broad pathological point of view the study of miners' phthisis is of interest mainly because of the light it may throw on the influence of accessory factors on microbic infections in general. Unfortunately the data in the report would scarcely seem capable of affording much assistance in the elucidation of this question. It may be noted that the evidence available does not lend any support to the view that silicosis and chronic interstitial nephritis are in any way related.

A CLASSICAL CASE OF MISTAKEN IDENTITY.

Just 20 years ago, in The Lancet of Dec. 3rd, 1904, we had occasion to comment on one of the most disquieting errors of identification in the annals of medico-legal history. A brief outline will recall the curious story. In 1877, 1895, and 1904 a man of German origin known as John Smith, and by various aliases, made a practice of robbing women, mostly prostitutes of the humbler class, of small sums of money and of rings and other articles of no great value, imposing upon them by giving himself fancy titles and by handing them what purported to be cheques, which were, of course, drawn on fictitious accounts. In 1877 Smith was convicted and sentenced to five years' penal servitude. In 1895 he avoided detection because a man called Adolf Beck, a Norwegian by birth, who, unfortunately for himself, was a needy adventurer of no good character, was mistaken for Smith by one of the women whom the latter had defrauded, and was arrested on her complaint. Several other women came forward and made the same mistake, for Beck, no doubt, bore a superficial resemblance to Smith in stature, face, and manner of dress. A communication made to the police, who had quite forgotten Smith, caused them to identify Beck as the former convict, at a date when a loose and unmethodical system of dactylography prevailed. Beck was tried at the Old Bailey before Sir Forrest Fulton, who had prosecuted Smith in 1877, was convicted and sentenced to seven years' penal servitude. The Common Serjeant, as Sir Forrest Fulton then was, helped to perpetuate the error of the police by shutting out the defence which Mr. (afterwards Sir) Charles Gill endeavoured to raise—namely, that the crimes of 1877 and those before the court, owing to the similarity of the methods adopted, must have been perpetrated by one and the same man, and that Beck was not in England when the first series were committed.

Beck went to prison as a previously convicted person, and although while at Portland he established the fact that he was not Smith, by proving that he had not been circumcised, whereas Smith had, he only succeeded in having his prison badge altered. At this point the Home Office and Sir Forrest Fulton were given the opportunity to set wrong right and failed to do so. Beck made every effort, as did his solicitor, to have his case properly investigated, but from his arrest to the day when he was finally declared innocent he was the victim of a lack of coördination and collation, of sympathy, industry, and intelligence on the part of police (who were least to blame), of prison authorities, lawyers, Treasury, and particularly the Home Office that gave a rude shock to some complacent people when the various stages of the muddle were gone into. This elucidation probably would never have taken place if Beck had not been arrested and tried again in 1904 for more offences of the same kind committed by Smith. Beck was found guilty, but Mr. Justice Grantham, who later professed to have had doubts about his guilt, had postponed sentence, when meanwhile Smith, whom success must have made reckless, having continued his evil acts, never even varying his methods, was caught red-handed. An intelligent detective, Mr. Kane, then recognised the fact that Smith and not Beck was the guilty man, and through his action at last justice was done. The interest of Beck's case lies largely in its exposure of the fallibility of justice, however honestly and impartially administered, and of the fallibility of more or less interested or revengeful witnesses when trying to identify a prisoner upon a carelessly observed resemblance.

This case was one of the principal causes of the institution of the Court of Criminal Appeal, and is now fitly included in the excellent notable British Trials Series.[1] Mr. Eric Watson, whom we should describe as editor rather than as author of the volume, has contributed a clear and exhaustive introduction, and has brought together material from official sources sufficient to make the book an interesting record of an historic miscarriage of justice. Several minor points are of especial interest. For example, the "cheques" given in the two cases of 1874 and 1895–96 proclaimed themselves the work of one man, and Mr. Watson might have made this even clearer if he had been able to include in his illustrations reproductions of one or two of these documents relating to each period. A great deal was made after Beck's final acquittal of the point of circumcision referred to above, but comparison of the official descriptions of the two men showed that even the colour of their eyes and the distinguishing marks on their bodies differed. And if this was not enough, there were extant photographs of both taken in prison. Profile photographs of Smith and Beck, reproduced by Mr. Watson, show that, unless the prisoner of 1896 had entirely altered the shape of his ears in 20 years, adding to them lobes non-existent when Smith was at Portland, a different man was being charged with exactly the same crimes in 1896 and in 1904. The wrong identification of Beck, which even eventually confused him with Smith, was as inexcusable as was the failure of the Common Serjeant and the Home Office to recognise the true nature of his defence. The giving of evidence by accused persons, the finger-print system of identification, the Court of Criminal Appeal, and the mitigation of sentences are improvements in our penal system of which we may justly be proud, but a careful study of Beck's story is nevertheless to be commended to lawyers and to judges.

Dr. Mary Lucas-Keene has been appointed to a chair of anatomy in the University of London, tenable at the London (R.F.H.) School of Medicine for Women. This is the first chair of anatomy to be held by a woman.

Annotations.

"Ne quid nimis."

TEACHING ON CONTRACEPTION IN MEDICAL SCHOOLS.

THE need for disentangling the medical from the racial and religious aspects of contraception is manifest to those who have attempted to follow the swings of the pendulum in the libel action, Sutherland *v.* Stopes, which has come finally to rest in the House of Lords after violent oscillations. The House, by a majority, allowed the appeal from a judgment of the Court of Appeal, the result being the restoration of the judgment of the Lord Chief Justice of England for the defendants in the original libel action—Dr. Halliday Sutherland and his publishers and printers. Previous stages of this action have been recorded in THE LANCET (1923, i., 504; 1923, ii., 236), and we may have occasion to return to the consideration of the legal aspects. In the meanwhile, we would draw attention to the fact that the decision in this case has no bearing on the broad problems of birth control. The Lord Chancellor, in giving judgment, saw fit to exclude from the concern of the House "any question as to the desirability of the use of contraceptives, or as to the propriety of encouraging such use by the circulation of printed matter, or in any other way." Lord Wrenbury, however, in his dissenting judgment, commented on the indirect issues involved. He said there were cases in which the health and happiness of the woman were impaired by too rapid successions of conception. There were cases in which the parents' means did not allow of the proper maintenance, education, and advancement of more than a limited number of children. There were cases in which the mental or bodily health of the parents forbade or ought to forbid the procreation of defective children. Again, there were those who thought that in none of these cases ought control to be exercised. There were those who thought otherwise. In both of these categories will be found eminent doctors. It is unlikely that uniformity of thought could yet be present either on the main question whether contraception is ever justifiable or even, if the principle is accepted, on the technique least likely to do harm. For example, Prof. Louise McIlroy was quoted as having stigmatised the check pessary as the most harmful method of which she had had experience; other specialists could doubtless be found who would prefer it at least to coitus interruptus. The majority of young doctors would readily admit that the subject was not referred to in their curriculum, and that they are not competent to weigh the social and domestic consequences of enjoining complete abstinence in married people who for economic or medical reasons should not produce a large number of children, against the alternative of giving instruction in appropriate methods of contraception.

A timely demand for critical instruction on this and cognate points from the medical rather than the emotional standpoint is made by Mr. C. P. Blacker in a survey of the subject published in *Guy's Hospital Gazette* of Oct. 11th. The essential point of his letter is a plea for the instruction of medical students in the principles and technique of contraception. We ourselves urged this course nearly four years ago [1] on the same grounds—that the apathy of medical men is largely responsible for the general dissemination of knowledge of birth control from an emotional rather than a medical angle. Nor is it only on this aspect of sexuology that text-books are silent. Mr. Blacker cites as untaught the period after conception during which sexual intercourse may properly be continued and the period after labour at which it may safely be resumed. Incidentally, this latter point might well have a bearing on the incidence of sepsis after childbirth. We commend Mr. Blacker's exposition of the problems of contraception as worthy of careful study. He has made out a good case for the inclusion of a chapter on birth control in every manual of obstetrics, and it is unlikely that the subject can much longer be ignored in these works.

THE HEALTH OF MERCHANT SEAMEN.

THE Conference of Port Sanitary Authorities, meeting at the Liverpool Congress of the Royal Sanitary Institute in July, forwarded to the Council of the Institute two resolutions, the first complaining of the inadequate report on the deaths of seamen put forward this year by the Board of Trade, the second asking that the health of seamen should be the care of the Ministry of Health. These resolutions have now been considered by the Parliamentary Committee of the Institute, which has suggested to the Board of Trade that the classification of the deaths of seamen should be remodelled on the lines of that adopted by the Registrar-General for the use of local authorities, and has also decided to forward to the Board of Trade and to the Ministry of Health a resolution urging that the care of the health of seamen should be given in charge of the Ministry of Health. The Royal Sanitary Institute is doing good work in thus keeping before the official gaze the need for the supervision of the health of merchant seamen.

MEASLES TWICE.

IN a festal number of the *Wiener Klinische Wochenschrift*, issued at the time of the Innsbruck meeting of the Society of German Naturalists, Prof. Johann Loos writes about second attacks of measles. He is speaking from personal experience at the Children's Clinic in the University of Innsbruck and from recent critical studies of the literature, and he answers the question submitted to him just in the same way as the author of snakes in Ireland was answered. There are, he says, no second attacks of measles. Prof. Loos does not go so far as to contend that no human being can get measles twice, but no convincing case of second attack has ever come before his own notice, and the three cases he relates, in which the opposite seemed to be true, are instructive in showing the kind of evidence on which honest but faulty conclusions are based. The first concerned a child brought to his department with undoubted measles and the statement that six months previously the child had had an attack in the clinic diagnosed as measles by one of Loos's own assistants. The notes of the case when referred to were detailed enough to show that this attack had been one of rubella; no second case of measles had followed on it. The second related to a teacher's family of nine children, who all had uncomplicated measles about the same date and recovered. A year later the eight-year-old daughter came to the clinic with a typical attack of measles. The parents were at first confident that this child had suffered along with the others, but on being pressed admitted to having overlooked the fact that she had spent her summer holiday with friends at the time of the occurrence and had consequently escaped. The third case was that of an assistant in Loos's clinic, who had what looked very like measles at the time of an epidemic in the clinic, although he had certainly had measles as a child, when his sister died of it. The absence of Koplik spots satisfied Loos that the present attack was one of influenza associated with a drug rash, and he was confirmed in this conviction by the fact that this assistant had been in contact with many cases of measles in recent years without becoming infected. Prof. Loos supports his own convincing personal experience by citing numbers of authorities who agree with him—Meissner, Bohn, Jürgens, Filatow, and others. Having critically examined the series of cases where his own experience might so readily have led him to form a faulty conclusion, he sets aside as irrelevant all the current loose talk of second attacks. Chicken-pox and mumps he has never observed twice, and he doubts if he has ever seen a second attack of whooping-cough.

MIDWIFERY, ANCIENT AND MODERN.

The issue by The Lancet of a Special Supplement on Modern Methods in Abnormal and Difficult Labour has moved an archæological contributor to send us notes upon eighteenth century midwifery for contrast. The notes consist mainly of comments on the advice given in the well-known work of Hugh Chamberlen, which was itself a translation of the text-book of François Mauriceau, "sworn master Chirurgen of Paris." From the period of the later Stuarts onward to that of George II. and George III., this was the standard text-book on midwifery and the diseases of women in England, and in its English form appears as the "Diseases of Women with Child, and in Child-bed." It was first published in 1683, and the third edition is of date 1697. The translation is interesting not only because it was the source whence the early men-midwives such as Smellie and William Hunter derived their knowledge in their student days, but also as showing how rational on the whole had been the craft or practice of midwifery from remote times to a period when surgery and medicine may be said to have become modern. "The work shows," writes our correspondent, "how an ancient form of knowledge evolved and gradually became free from mediæval absurdities. Chamberlen's translation ran through several editions, but in all the preface remains unchanged. It contains the notable passage in which he refers darkly to the secret method employed by his family in cases of difficult labour. This was quoted at large by Dr. Aveling in his work on the Chamberlens, published in 1882. 'I will now take leave to offer an apology,' says Hugh Chamberlen in a closing passage of his preface, 'for not publishing the Secret I mention: we have to extract children without Hooks, where other Artists use them—viz., there being my Father and two Brothers living, that practise this Art, I cannot esteem it my own to dispose of, nor publish it without injury to them. Still,' (he continues), 'we four are the people who can serve the public in their extremities with greater safety than the persons who extract the child from the womb with the help of hooks fixed in the neck.' The Chamberlens kept their secret, the use of the midwifery forceps, till well on in the eighteenth century, when poverty compelled Hugh, the elder, to sell it to a Dutch obstetrician named Roonuysen. Thus, the preface to a work in the main rational refers to a trade secret, and in so far as it does that belongs to a vanished period of medical procedure." "Here and there throughout Mauriceau's work," continues our correspondent, "mediæval curiosities survive and are sometimes allowed to pass without protest by the translator, whose marginal notes are at other times full of common sense. Thus 'we'll now pass to convenient remedies for the belly of a new-lay'd woman,' says Mauriceau. 'All authors do appoint, immediately after delivery, the skin of a black sheep flaid alive, for this purpose, to be laid all over her belly, and to lie on four or five hours; others will have a hare-skin. Truly, I believe that by reason of the natural heat of such skins, the remedy is not bad.' But it is 'of too much trouble,' for a butcher must be at hand in the lying-in room, 'or at least in the house, that so they may have the skin very hot according to directions.' The same work likewise directs 'a small plaister of galbanum, with a little civet in the middle,' to be applied to the woman's navel, which as they imagine is very proper to keep the womb in its place, because being delighted with that smell, it draws near to it of itself." . . . "But this remedy is a little superstitious," adds Mauriceau, yet 'practice and success commend it' (comments Chamberlen). "Nor is there reason wanting to defend it; wherefore notwithstanding the author's sense, it may be successfully continued."

The use of the colour red as a cure or prophylactic takes us back to the medicine of savages. Thus a pregnant woman injured by a fall was often advised by the midwives and by some authors of Mauriceau's period "to take some crimson silk, small minced in the yolk of an egg, or the grains of scarlet [kermes, derived from "the grains of the scarlet oak," *Bailey's Dict.*, Edit. 8, 1737], and treddles of several eggs put into the yolk of one, as if that entring the stomach were able to fortify the womb and the child in it, and to keep it there." Mauriceau is of opinion that reason and truth are against this, but Chamberlen asks, if this be so, "how then do inward medicines either prevent miscarriage or forward travail?" To prevent "headmouldshot," a condition referred to in old bills of mortality, which has puzzled the moderns, a Frenchwoman often applied a piece of scarlet cloth to the child's head and kept it there for some time. Mauriceau devotes a chapter with two illustrations to headmouldshot, and entitles it "Of the mould of the head, and of the sutures being too open," the first explanation we have seen of the phrase. "Shot" is written "shotten" by Chamberlen, and "shotten" is explained by Bailey in his dictionary as "curdled," or, better still, as overlapping. Red curtains, Mauriceau notes, are hung by some round the bed of a child ill of small-pox, "because this colour doth ordinarily move the humours from the centre outwards . . . many antient as well as modern physicians attribute the cause of the disease to the residue of the menstrous blood, wherewith the infant was nourished in the mother's womb." Chamberlen, tending towards rationality, prefers green to red as being more soothing to the eyes. He notes on several occasions that French methods differ from English in such matters as swaddling and the bandaging of the baby head. Mauriceau's long description of his sister's tragic death from flooding, when before the age of 21 she was brought to bed of her *fifth* child, does not surprise his commentator, who imagines similar cases in England to be caused by the vanity and ignorance of midwives and physicians.

ON THE MUSCULATURE OF THE LUNGS.

Except in the case of asthma the pathologist and clinician are both alike inclined to overlook the importance of the musculature of the lung, and a careful piece of work by Dr. Joseph Harkavy in the *Journal of Pathology and Bacteriology* (October, 1924) is a timely contribution to this subject. Starting from the histological work of Husten, Miller, and others, the writer points out that the entire lung is extraordinarily well supplied with musculature, and goes on to ask the pertinent question what is the function of this musculature and what alteration takes place in disease? With these questions in view he investigated 176 lungs obtained from cases of cardiac disease, pneumonia, broncho-pneumonia, and pulmonary tuberculosis. Excluding the cases in which no changes in the musculature were found, the writer divided his positive findings into four groups. The first group contained lungs from cases of cardiac disease. Here was found marked increase in the musculature of the alveolar passages and of the muscle ring of the bronchiolus respiratorius, occurring most commonly in pure mitral stenosis. Elastic tissue was also found to be increased. In the second group were lungs from cardiac cases in which pulmonary induration and pleural obliteration were present, and these showed a more general increase of musculature affecting the indurated lung parenchyma, vessels and septa, and especially marked in areas of scars and indurated pleura. The third group contained cases of total pleural obliteration with evidences of old tuberculosis, in which the increased musculature was chiefly evident in the interstitium and in the quantity of the muscle sheets in the thickened pleura, with new-formed blood-vessels, multiplication of pleural elastic tissue fibres, and hypertrophy of the muscle round about the areas of compensatory emphysema. The fourth group comprised cases of emphysema, pulmonary cirrhosis following pneumonia, anthracosis and pulmonary œdema of nephritic origin, and were characterised by the irregular nature of the muscle hypertrophy, some areas showing marked hypertrophy and others none. The changes seen were chiefly thickening of the muscle of the alveolar pillars, of the alveolar passages, especially in the vicinity of pleura and septa, wherever chronic obstruction to expiration had taken place. After discussing various possible theories of causation of hypertrophy of this system of musculature the writer points out that two forces are concerned—viz., movement of the chest wall and respiratory action of the lung proper. When the former is restrained by disease, compensatory hypertrophy of the musculature of the lung results. That this musculature takes an active part in respiration is clear, and its response to disease by increased action on the arterial side of the alveolar passages, on the large vessels of the interstitium, and the lymphatics of the septa, therefore, seems likely. Many years ago S. West[1] suggested that we might "compare the lungs with the arteries and speak of 'pulmonary tone' just as we do of 'arterial tone,' and connect the tone in the lungs as we do in the arteries, with the condition of the muscles, and possibly of the nerves." In an article containing some beautiful illustrations of the musculature of the lung, W. S. Miller[2] has further shown that the bronchial musculature is arranged very much in the form of a network made up of geodesic bands which prevent any tangenial motion, thus permitting the greatest amount of extension and contraction of the bronchioles and their subdivisions., Muscle bands, indeed, penetrate much further along the ramifications of the bronchial tree than physiological text-books would lead us to suppose; they extend as sphincters to the openings of the alveoli into the bronchioles respiratorii, but there is no muscle in the walls of the air spaces. The implications of these researches may be considerable; vital capacity and the phenomena of dyspnœa as applied to emphysema and other chronic pulmonary diseases must all depend, amongst other factors, upon the bronchial musculature—an anatomical mechanism hitherto only very imperfectly understood.

NICE NOISE.

THE dreadful noise of towns becomes worse and worse. Complaints reach us from various sources of the loss of sleep occasioned thereby in hospitals and nursing homes. Some physicians and surgeons regard this noise as a serious impediment to their patients' chance of recovery, and at the least it tends to retard convalescence. Mr. E. V. Lucas has described the motor-bicycle with internal trouble as the second noisiest thing he knows; and the editor of *Psyche* includes it in a leading article with the new form of pavement breaker and alludes to the gratuitous and ever-increasing hubbub of newsboys, street organs, bells and the like in residential areas. Time was when such noises were more or less confined to business areas, but they are now ubiquitous. The remedy is hard to seek. It is impossible to fit bedrooms in nursing homes and wards in hospitals with double-paned sound-proof windows without interfering with the necessary ventilation. The patient may plug his ears and so obtain a quiet night, but it is not everyone who can tolerate the presence of a meatal tampon. It seems too much to hope that the motorist can be induced altogether to abandon the use of his hooter after dark, although, as Sir Lenthal Cheatle has pointed out, with careful driving most of the motor-horn emissions are quite unnecessary. Persons in rude health are able to focus unpleasant noise on their deaf spot and find it hard to realise, until they are ailing themselves, how noise may rack the nerves of others. .

A temporary solution is probably to be found in the substitution of nice noise for horrible noise. Sir Henry Hadow's address on Wednesday at the Royal Hospital, Chelsea, was devoted to the healing influence of music, and Sir Bruce Bruce-Porter has attributed the high turnover of a hundred beds per month at the Third London General Hospital during the war to the distraction provided by gramophones and concerts. The distinguished pianist, Mr. Moissye Boguslawski, invited to the wards, at the instance of the staff of the Chicago State Hospital, never found an individual who did not respond in some way to rhythm, and Dr. Michael Grabham writes this week in our columns on personal experience of the therapeutic value of music. Folk-songs seemed to have special value. The Chicago Commissioner of Health remarks that the nurse or hospital attendant who hums or sings softly while near the patients seems to inspire confidence and contentment. That may have its risks, and all these means are only available to some on a few occasions. But the advent of wireless transmission has brought the temporary bedrid into touch with beautiful sounds by the mere turning of a button. In another column we set out some of the facilities as they exist at present for convalescent patients to obtain wireless sets. No doubt the supply will increase as the need for them is realised. The demand is sure to come.

EPIDEMIC DIAPHRAGMATIC PLEURISY.

IN the October number of the *American Journal of the Medical Sciences* Dr. Robert G. Torrey, of the Philadelphia General Hospital, states that during the summer of 1923 an epidemic occurrence of an acute febrile condition characterised by severe pain in the epigastrium or chest was reported to the State Board of Health of Virginia by Maude M. Kelly as observed by her in two counties of the State. A subsequent report was made under the heading of "epidemic, transient, diaphragmatic spasm," by Payne and Armstrong,[1] who regarded their series of cases as representative of a fairly widespread epidemic, and considered the condition to be a definite clinical entity. The disease was prevalent in the latter part of the summer of 1923 in the Middle Atlantic States, particularly Virginia and New Jersey, where it was popularly known by the name of "Devil's grip." Dr. Torrey, who records four illustrative cases in adults, states that the onset is sudden and often accompanied by a distinct chill, the temperature rising to 102°–104° F., and the pulse usually following the temperature. Pain is the main symptom, occurring in the epigastrium or back or in the lower part of the chest. It is aggravated by breathing or by movement. It is increased during the febrile attacks and decreased as the temperature drops. With the pain there may be marked tenderness which may persist after the pain has disappeared. There may be only one attack, but there are usually recrudescences of pain and fever occurring at intervals of 24 or 48 hours. Headache is a usual symptom and is generally frontal. Profuse sweating is characteristic and occurs late. Prostration is not marked as in influenza. There is an absence of lung involvement and pleural friction has not been heard. The knee-jerks may be diminished or lost, but promptly return to the normal. The prognosis is good. No deaths have been reported. As a rule recovery is prompt and complete. The pain is probably due to involvement of the diaphragm or diaphragmatic pleura. The headache and reflex nervous disturbances indicate some degree of nerve tissue involvement by the toxin. In the same number of the journal as Dr. Torrey's article Dr. James C. Small describes under the name of *Plasmodium pleurodyniæ* a protozoan organism which he has found within the red cells of patients suffering from the disease, different stages in the cycle of its development being observed. The organism is differentiated from those of the malarial group in its staining characters, morphology, absence of pigment granules, and lack of a distinctive action on the contiguous portion of the red cell enclosing it.

EFFECT OF RICKETS ON GROWTH.

AN important addition to the literature on this subject has just been made by Dr. George Rose in his annual report to the Aberdeen Educational Authority. Following up an inquiry made in 1911 and 1912 into the incidence and consequences of rickets among 5-year-old entrants he now publishes the results of examination of the same children eight years later. The investigation was carried out in four school terms of 1911 and 1912. All entrants of 5 years of age were examined by Dr. Rose himself, special attention being given to signs of rickets. The children examined totalled 3742, a number quite sufficient to put the inquiry on a statistically sound basis, and an average of 37·4 per cent. showed signs of rickets. Children from poor homes were most frequently, and most seriously, affected. The average heights and weights of rickety and non-rickety children were then compared as follows:—

	Boys.		*Girls.*	
	Height in inches.	Weight in lbs.	Height in inches.	Weight in lbs.
Non-rickety	41·5	40·9	40·8	39·4
Rickety	39·9	36·7	39·5	34·7
Difference	1·6	4·2	1·3	4·7

Eight years later, having reached the age of 13½, the same children came up for examination by Dr. Rose, and practically the same proportion, 37 per cent., showed traces of rickets. They were again lower in weight and shorter in stature:—

	Boys.		*Girls.*	
	Height in inches.	Weight in lbs.	Height in inches.	Weight in lbs.
Non-rickety	56·2	82·0	57·6	83·0
Rickety	54·1	72·9	55·0	72·4
Difference	2·1	9·1	2·6	10·6

These investigations show how, with the exception of certain individual cases, chiefly among the well-to-do, the child who has suffered from rickets in early life will, at 13 years of age, be considerably under the average height and weight of the normal child, and Dr. Rose points out that the presence or absence of rickets is an important factor in assessing the average height and weight of older children. "While by taking thought we cannot add a cubit to our stature," he writes, nevertheless, "by proper dieting and good hygiene it would be possible to add two to two and a half inches, and from nine to ten and a half pounds, to the height and weight of over a third of our 13-year-old boys and girls, which would increase the average heights and weights in the community."

MYOSITIS INFECTIOSA.

AN account of seven cases of myositis infectiosa, treated in a hospital in Upsala, has recently been published in *Acta Chirurgica Scandinavica* (Vol. LVII., fasc. v., 1924) by Dr. Göran Holm, who points out that this term should not, according to some authorities, be applied to any and every case of metastatic infection of the muscles, but should be reserved for those cases of acute purulent inflammation of the muscles in which they are the first or only localisation of the disease. Its geographical distribution seems to be very uneven: Japanese writers have recorded as many as 250 cases. Men are more subject to it than women, and of the 56 cases collected by Dr. Holm in which the sex of the patient was recorded, as many as 38 were males. In most cases the onset of the symptoms is fairly acute; there are rigors, fever, and pain in the muscles involved. In two of Dr. Holm's cases the transition from feeling well to feeling very ill was as abrupt as if a gastric ulcer had perforated. But, as another of Dr. Holm's cases showed, and this case terminated fatally, the onset of the disease may be insidious, and for a week or more there may be ill-defined influenzal symptoms. Between these two extreme types there are various transitional forms. The first local sign is spontaneous pain in the muscles, which on palpation and active movement become still more painful. When the characteristic swelling has developed there is no longer any excuse for ascribing the pain to "rheumatism," and as the local reaction grows in intensity the muscle may become very hard. This muscular rigidity tends to disguise even a large abscess within the muscle, and though it may be difficult to demonstrate fluctuation, an incision sometimes yields much pus. Muscular rigidity is apt to prove deceptive, and in this connexion Dr. Holm refers to the case of a 9-year-old girl in whose thigh muscles a swelling, fully as large as a hen's egg, could be felt when she was admitted to hospital. Under treatment with fomentations and rest in bed the swelling disappeared almost completely, and it reappeared only after vigorous palpation in search of the tumour had again made the muscles contract. They remained hard and contracted for at least ten minutes. The large muscles of the limbs, the gluteal muscles in particular, are most subject to this condition, whereas the muscles of the abdomen and back are seldom involved. As a rule, only one muscle is diseased, but cases in which there are two or three different localisations are not altogether rare. Two of Dr. Holm's seven cases terminated fatally. Staphylococci were found in three cases, streptococci in one, and a mixed infection with staphylococci and streptococci in another. Both these last two cases were fatal. The pus was sterile in another case, and in yet another case it was reabsorbed spontaneously. The treatment indicated in most such cases is free incision with adequate drainage.

THE MEETING OF THE FELLOWS AND MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A BRIEF account of the annual meeting of the Fellows and Members of the Royal College of Surgeons will be found in another column, in which once again the gathering passed a resolution, and not for the first time unanimously, that Members should be admitted to representation on the Council of the College. We have always considered this reform desirable, and we have said so often, but not with any idea of preserving continuity of action with the distinguished founder of this paper, for he had abuses of a very different character to deal with. To-day the Council is not self-elected, nor are examinerships held by veterans who have fallen behind the learning of the time, so that methods of protest, allowed to have been legitimate in the bad old days, are no longer called for. But as to the rightness of admitting a representation of the large body of Members upon the governing body of the College, there seems to us no doubt; exclusion is an anachronism, having regard to the spirit of the times.

THE four successful candidates, together with the votes polled by each, for election as Direct Representatives for England and Wales on the General Medical Council are as follows:—(1) Dr. H. B. Brackenbury, London, 11,486; (2) Dr. R. A. Bolam, Newcastle-on-Tyne, 10,087; (3) Sir Thomas J. Verrall, Bath, 9620; (4) Dr. J. A. Macdonald, Taunton, 9143.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The seventh meeting of the Commission was held at the Home Office, Whitehall, on Nov. 20th, Lord Lawrence, of Kingsgate, in the chair. Mr. E. J. Strohmenger, Accountant-General of the Ministry of Health, was examined on a variety of matters relating to the financial and accounting arrangements of the scheme of National Health Insurance. Thereafter a beginning was made with the examination of the representatives of the Hearts of Oak Benefit Society, Mr. Hezekiah Dudley, chairman of the Executive Council, and Mr. J. P. Lewis, secretary, who dealt with various questions relating to the constitution, membership, and financial position of that society, and the extension of medical benefit to dependents of insured persons. The Commission announce that the oral evidence given at the meeting of Nov. 6th is now on sale in proof form (1s. 6*d.*) at H.M. Stationery Office, Adastral House, Kingsway, W.C.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XCVIII.—THE TREATMENT OF CHRONIC BRONCHITIS AND EMPHYSEMA.

THE lot of the middle-aged or elderly bronchitic patient is a hard one and the task of his medical attendant is difficult, since the choice of treatment often lies between recommendations which are impracticable on the ground of expense, or uneconomic because they would prevent the patient from earning his living. Treatment is thus often of necessity a compromise and unsatisfactory from the patient's and, it may be, from the practitioner's points of view. Yet much can be done, even in unpromising cases, by a judicious use to the best advantage of preventive measures and palliative or remedial treatment. The association of bronchitis and emphysema is a true example of a vicious circle. The conditions of life and work in most parts of this country, especially in the towns, are often such as to fix the circle firmly in its harmful progression.

Prevention.

Climatic treatment.—Where possible, the patient should be moved from places where cold, damp, and fogs prevail to those with an equable, dry, and sunny climate, and where there are no prevailing cold winds. In this country, the health resorts on the south coast from Hastings to Falmouth or Penzance, including the Isle of Wight, and those on the Welsh coast—such as Colwyn Bay and Llandudno in the north or Tenby in the south—afford useful refuges for these patients; but even at such places they may be obliged to remain indoors for many days owing to unfavourable conditions of weather. Further afield, for those whose means permit, many of the resorts on the French and Italian Riviera, such as Hyéres, Cannes, Mentone, Nice, San Remo, and Alassio, are often recommended; but it should not be forgotten that at some of these places bitingly cold winds may occur, and that in crowded hotels catarrhal infections may be rife. Still further, the Egyptian desert stations, Mena House, Helouan, and Assouan, the Atlantic islands—Madeira, the Canaries, and the Azores, and places such as Jamaica, Cuba, and California all offer climatic conditions favourable to these patients during the months of the English winter. Patients endeavouring to escape catarrhal conditions in this country should leave before November and should not return till April at the earliest, and preferably May.

To many of the worst sufferers recommendations of this kind are impossible, from family, financial, and business reasons, and for such the conditions of life and work may require the most careful scrutiny. They may be advised to change their residence from a damp, foggy, low-lying or riverside locality to a healthy suburb or to another urban or rural district not too far away from the place of occupation. This is particularly the case where there is an asthmatic factor. It may sometimes be necessary for the patient to consider a change of occupation owing to the limitations imposed by the chronic and progressive nature of the malady. Dusty occupations are particularly to be avoided. In advanced cases where the patient is obliged to live in unsuitable places it may be necessary to keep him indoors for weeks at a time, or even for the greater part of the winter, only allowing a walk, drive, or other outing when the weather conditions are favourable.

Clothing.—Bronchitics nearly all have an almost morbid fear of "chill"—which is justified to the extent that it is generally admitted that marked chilling of the surface of the body may lead to congestion of the bronchial mucous membrane and to acute exacerbations of catarrhal processes. It becomes morbid when it leads the patient, as is so often the case, to put on extra vests, home-made or bought "chest protectors," or thick jackets of cotton-wool, medicated or otherwise. Once employed, these are difficult to discard, and, at each fresh sensation of cold, an extra layer is often applied till the patient is literally swathed in multiple wrappings. By promoting sweating, these measures render the patient uncomfortable and favour, rather than prevent, chill. Warm underwear of loose cellular type, either wool or linen, should be worn, with warm wool-lined waistcoats or cardigans in the case of men, and Shetland or other woollen spencers in the case of women. Sometimes two light cellular vests are to be preferred to one heavy impervious woollen garment. For outdoor wear, warm rather than heavy clothing should be worn. Scarves or "mufflers" are not to be encouraged, but they may be permitted, provided they are worn so as not to cause sweating.

Vaccines.—Prophylactic inoculations may afford valuable aid in the prevention of acute catarrhal infections. Where it is known that one particular organism is concerned, an autogenous vaccine may be used, but as a rule one of the stock "mixed" vaccines seems to give satisfactory results. The stock vaccine has the merit of being simpler and cheaper than an autogenous vaccine. Not a few patients, especially those with some chronic indurative process in the lungs, prove sensitive to these vaccines, and may develop acute symptoms after each dose. In such cases small doses should be used to start with in subsequent courses, and only slowly should the ordinary doses be reached. In some cases the prophylactic vaccination may have to be discarded.

Nose and throat.—The nose and throat should be carefully examined, and any abnormal condition, such as nasal obstruction, chronic diseases of the accessory sinuses or polypi, dealt with.

Diet.

Since not a few patients suffer from arteriosclerosis, heart weakness, or asthma, a light diet —poor in nitrogenous constituents—is advisable, and it is often wise to take the chief meal at midday rather than in the evening. Flatulence may promote useless cough, embarrass the heart, and increase the asthmatic or paroxysmal character of the dyspnœa. Alcohol should only be permitted in strict moderation. It is then more likely to be helpful in emergency. Smoking should be cut down or prohibited in severe cases, especially the inhaling of smoke.

Drugs.

The medicinal treatment varies with the type and degree of the condition. The classification of the cases which is usually adopted is based on that of Laennec. There is (1) the *ordinary winter cough or chronic tracheo-bronchitis*, the commonest variety. In such cases but little medicine may be necessary. A simple expectorant mixture of vin. ipecacuanhæ ♏ x., syrup. scillæ ʒ i., tinctur. camphoræ co. ♏ x., aquam chloroformi ad ℥ i., to take occasionally may be all that is necessary. Where cough is frequent, irritative, and ineffective, a dose of the well-known Brompton Hospital "mist. sodæ cum æther. chloric." taken in hot water may be helpful. It consists of sodium bicarbonate gr. x., sodium chloride gr. iii., spiritus chloroformi ♏ v., aquam anisi ad ℥ i. In cases with marked tracheitis, small doses of apomorphine (1/36–1/20 gr.) and of morphine in the form of tincturæ chloroformi et morphinæ, '85 B.P. (♏ v.–x.) are often very useful. Various demulcent or sedative lozenges, such as the black currant, the glycerine, the liquorice, the ipecacuanha, or ipecacuanha and morphine lozenge, or one with a small dose of heroin, are all of value in certain cases.

(2) *In more severe cases* with asthmatic dyspnœa or with copious nummulated muco-purulent sputum, iodides, ammonium salts (the chlorides or carbonates), and antispasmodic drugs, such as belladonna, stramonium, hyoscyamus or grindelia, may be useful.

A valuable mixture in such cases is pot. iodid. gr. iii., pot. bicarb. gr. x., ammon. carb. gr. iii., tinct. stramonii ♏ v.–x., syrup. tolut. ʒ i., aq. chlorof. ad ℥ i.

(3) *Bronchorrhœa*—the "pituitous catarrh" of older writers. This uncommon condition is a distressing one, owing to the very large quantity of sputum which is brought up. It may reach as much as 4 to 5 pints in 24 hours. It is thin, watery, frothy, and non-albuminous. Treatment seems to exert but little influence on it, but atropine, belladonna, acids, and vaccines may all be tried.

(4) *Dry catarrh*—in which little or no sputum is expectorated, but there is a chronic, distressing, and painful cough. In this type of case saline expectorants, such as the Brompton Hospital mixture above mentioned, with iodides give the best results.

Other drugs which have been employed in cases of chronic bronchitis are ammoniacum, terebene, creosote, garlic, the balsams, and the benzoates. Some of these are worth trial in cases which prove refractory. Cod-liver oil, with or without malt, is often helpful, especially in patients of thin, spare habit.

Local and Special Measures.

Counter irritation to the chest in the form of liniments often proves helpful and comforting to these patients, especially when there is retro-sternal soreness or muscular pain from violent or prolonged coughing. One of the best of these is the acetic turpentine liniment, but other stronger liniments or iodine ointments are often useful.

Dry cupping of the bases of the lungs may be useful during acute attacks, especially in older people, or those confined to bed and tending to develop hypostatic basic congestion. Poultices may also be used in similar conditions.

In cases with marked emphysema, various special contrivances have been designed to promote ventilation of the lungs—of these Kuhn's mask and the compressed air bath have proved the most helpful. The latter may help certain cases with dyspnœa and expectoration, but it is difficult to secure the treatment, and it is now not often used.

Vaccine treatment.—This seems to be of less value in treatment than in prophylaxis. It may, however, be tried cautiously in cases in which other methods fail. In this case an autogenous vaccine is to be preferred, in small doses at first.

Complications.

The chief complications for consideration are: (*a*) Attacks of acute bronchitis progressing to bronchopneumonia; (*b*) progressive emphysema; (*c*) cardiac failure; and (*d*) pulmonary tuberculosis.

(*a*) *Acute bronchitis* should be treated on ordinary lines. The patient should at once be put to bed, no matter how mild the attack may appear at the outset; saline expectorants, diaphoretics, and stimulants being given if necessary, and the physical signs watched.

(*b*) *Advancing emphysema* with increasing cyanosis demands a careful review of the patient's mode of life, occupation, and habits. In some such cases the compressed air bath proves of great value.

(*c*) *Cardiac failure*, which is more especially right-sided in these cases, requires most careful treatment. Rest, the relief of the engorged right side by venesection, leeching or purging, and the employment of cardiac tonics are the chief means at disposal. Venesection should not be employed in old, enfeebled, or cachectic cases.

(*d*) *Pulmonary tuberculosis.*—This should be suspected in cases in which the summer intermission suddenly ceases. It is wise in all cases to have the sputum examined, as it is now becoming more generally recognised that tuberculosis in the elderly often masquerades as senile bronchitis, or is masked by emphysema till it is advanced.

IS SANATORIUM TREATMENT JUSTIFIED BY ITS RESULTS?

A COMPARISON OF THE AFTER-HISTORIES OF 4000 LANCASHIRE SANATORIUM AND NON-SANATORIUM PATIENTS.

BY G. LISSANT COX, M.D. CAMB.,
CENTRAL TUBERCULOSIS OFFICER, LANCASHIRE COUNTY COUNCIL.

THERE have been in recent years many unfavourable opinions passed on the results of sanatorium treatment of patients suffering from pulmonary tuberculosis. Some of the more severe critics have openly stated their conviction that the money expended on this form of treatment is as good as wasted and could be better employed in other benefits to the patients by way of payment of weekly allowances or pensions, improved housing, and so on.

Fallacies of Comparative Figures.

It is unfortunate, I think, that in the past too hasty judgments have been formed on the results of sanatorium treatment based on data which gave no distinction between advanced and early cases, positive sputum and negative sputum cases, and young adults and old adults. To settle the superiority or otherwise of sanatorium treatment over other forms of treatment it would be necessary to compare one group of patients who have undergone sanatorium treatment with another group, exactly similar in age, sex, environment, location, and severity of the disease, who have received treatment other than in a sanatorium.[1] Such an experiment is not likely to be possible in this country, and any comparison we wish to make must, therefore, be based on less scientific data. The Medical Research Council have issued special reports (Nos. 33, 76, and 85) which give after-results of sanatorium treatment, but they have not yet attempted to make an investigation as to the relative merits of treatment at a sanatorium and at home. A comparison was made on a comparatively small scale by Dr. E. Ward, tuberculosis officer, Devon County Council,[2] with results unfavourable to sanatorium treatment, but the cases were not divided into age-groups, nor separated as to positive and negative sputum.

Method of this Inquiry.

For the administrative county of Lancaster, which contains a population of 1¾ millions, I have for the past three years (1921, 1922, 1923) published in my annual reports an analysis of the after-histories of a large number of patients that had undergone sanatorium treatment compared with the after-histories of patients similar, as far as possible, in age, sex, and severity of the disease that had *not* had sanatorium treatment. The patients taken for this investigation comprised all the adult cases of pulmonary tuberculosis, diagnosed as being in the early or intermediate stage of the disease, who applied to the county council for treatment during the years 1914–18, with certain necessary deductions for removals out of the county, untraceable cases, patients in whom the diagnosis subsequently was not confirmed, and those who died from causes other than tuberculosis. Patients that were in an advanced stage when first commencing treatment under the county scheme are not included in the analysis, as no useful purpose would be served thereby. Further, it is necessary to add that "sanatorium cases" mean patients that completed a stay of two months or more in a sanatorium, sent for probable arrest or cure of the disease (as distinct from a pulmonary hospital where treatment may have been given in the later stages of the disease), and that many of the "non-sanatorium cases" have also received treatment in a pulmonary hospital or observation hospital, or have had a stay of less than two months in a sanatorium, their treatment being interrupted for some reason or other.

[1] THE LANCET, 1924, ii., 831.
[2] THE LANCET, 1921, i., 531.

After-histories of Sanatorium and Non-Sanatorium Cases.

The net numbers of cases which remained for investigation were 4067 in 1921, 3948 in 1922, and 3868 in 1923. Through the dispensary staff the position, as at the end of the years named, of each case was ascertained, and from this information the after-results were classified. Space permits the publication only of the last prepared table, that for 1923:—

Analysis of After-histories of (1) 2228 Patients who have Completed a Course of Sanatorium Treatment, Associated with Dispensary Treatment or Supervision; and (2) 1640 Patients who have Undergone Treatment at Home or in Institutions other than Sanatoriums.

---

* Net number arrived at after deducting patients left county, untraced, ceased treatment for other than medical reasons, died from other than tuberculosis, diagnosis not confirmed, and in institutions on Dec. 31st, 1923.

† Where sputum is shown as positive, tubercle bacilli have been found at some time during treatment.

‡ Classified according to the system of Turban-Gerhardt, and further subdivided into cases with slight and severe constitutional symptoms, as suggested by Philip.

Conclusions.

The conclusions which may be formed from this table and those for the two previous years may be summarised as follows:—

1. As the result of the analysis of the after-histories of adults suffering from pulmonary tuberculosis who commenced treatment under the Lancashire county scheme during the five years 1914–18, so far as comparison is possible, patients in the *early* and *intermediate* stages of the disease that have undergone a course of sanatorium treatment, even for three or four months, fare appreciably better in later years than those that have not received such treatment.

2. Differences in the mortality of the sanatorium and non-sanatorium patients are given below:—

—	Patients with negative or absent sputum.			Patients with positive sputum.		
	1921	1922	1923	1921	1922	1923
Percentage of sanatorium cases that had died at the end of the year stated	14·0	16·0	17·0	61·2	66·2	69·2
Percentage of non-sanatorium cases that had died at the end of the year stated	37·7	42·6	45·3	81·3	84·8	87·4

The difference in favour of sanatorium treatment is considerable for the negative or absent sputum cases, and nearly 20 per cent. for the positive sputum cases.

3. It would appear from the table that in the age-group 15–25 of the *positive* cases sanatorium treatment, merely regarded from the point of prolongation of life, is very little better than home treatment. It must never be forgotten, however, that from the more important side of prevention of the disease a stay in a sanatorium has, in the main, a definite educational result on the patient, his family, and his friends.

4. In both sanatorium and non-sanatorium cases early diagnosis is a very important factor in the successful treatment of pulmonary tuberculosis.

5. In both of the groups those patients with a negative or absent sputum throughout treatment are much more likely to remain fit for work, and less liable to succumb to the disease, than those with tubercle bacilli in the sputum.

6. Also, in both of the groups the mortality from pulmonary tuberculosis is greater among patients, aged between 15 and 25 years, with a positive sputum, than in the other age-groups.

Given reasonably early cases for treatment and an institution with a capable superintendent, the result of the investigation is in favour of sanatorium treatment.

UNIVERSITY OF BRISTOL.—Post-graduate demonstrations will be held at the Swindon Town Club on Wednesday, Dec. 3rd, at 3.15 P.M. The subject is Dyspepsia: Some Considerations for Diagnosis and Treatment, by Dr. Carey Coombs.

A WIRELESS EQUIPPED HOSPITAL.—The installation recently inaugurated at the Haywards Heath Hospital includes a four-valve wireless cabinet with head-phones connected with practically every bed in the wards, on the tidy-phone system. A movable loud speaker is included so that in the nurses' recreation-room concert and dance music can be enjoyed. The cost of the installation has been about £80. The inauguration ceremony was attended by a number of practitioners from Brighton and the surrounding district. Dr. Geoffrey Bate spoke to the patients by means of a microphone. He said they were in a hospital which was unique, because, as far as he knew, there was no other hospital in the country so completely equipped with wireless. The installation showed that they were doing everything to make the patient's stay in hospital cheerful and bright, which tended to hasten their recovery. Dr. Bate hoped it would encourage them to regain their health, but not encourage them to stay in hospital.

SURGICAL BOOTS.

BY CHARLES MACKAY, M.D., B.S. MELB.,
MAJOR, R.A.M.C. (HON.); MEDICAL OFFICER IN CHARGE OF ORTHOPÆDIC CLINICS, MINISTRY OF PENSIONS;

AND

D. DENHAM PINNOCK, F.R.C.S. ENG.,
ASSISTANT SURGEON, LONDON TEMPERANCE HOSPITAL AND VICTORIA HOSPITAL FOR CHILDREN; MEDICAL OFFICER IN CHARGE OF ORTHOPÆDIC CLINICS, MINISTRY OF PENSIONS.

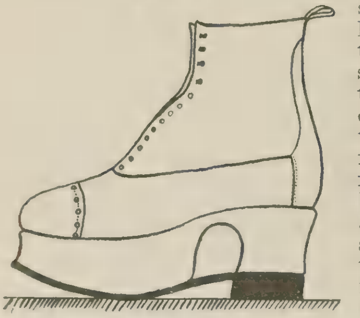
(*Concluded from p. 1085.*)

II.—GENERAL APPLICATIONS.

Shortening of the Leg.

WE will first consider simple shortening of leg without deformity of foot. If, for example, the shortening is 2½ inches, then the surgical boot should be raised inside with cork about 2 inches at the heel, 1 inch at tread, and ½ inch at toes. The tread is taken to be that part of the boot corresponding to the heads of the metatarsal bones. If shortening is more than 2½ inches, it is often more satisfactory to have the cork raising outside (Fig. 8), not inside (Fig. 9) the boot. The appearance of the boot is not so satisfactory, but the weight has been reduced, and the boot retains its shape and wears better. Shortening of the leg may be real or apparent.

FIG. 8.

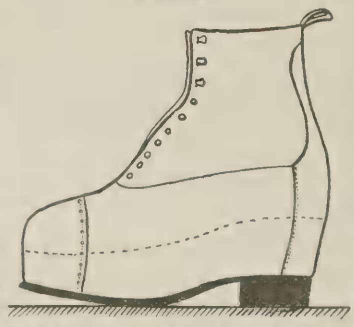


Surgical boot with outside "box" or "bridge" cork.

Methods of measurement for shortening are as follows:—

(*a*) *True shortening.*—In order to be accurate measurements should be taken with a metal tape from the anterior superior spine of the ilium to the tip of the internal malleolus, with the patient recumbent and properly stripped. This measurement should be taken at least twice on each side, and if no pelvic tilting is present, it can be checked with the patient standing, by means of graduated cork blocks of known thickness.

FIG. 9.



Surgical boot with inside cork. Note the "roll" or clearance at toe.

(*b*) *Apparent shortening.* — Where pelvic tilting is present, the above measurement may be vitiated. It is necessary under these circumstances to measure from a central point such as the umbilicus to the tip of the internal malleolus. Where pelvic tilting is a fixed deformity, such as occurs following injuries or disease in or about the hip-joint, this latter measurement must be the basis for any compensatory raising of the surgical boot. Owing to the adduction of one limb and the abduction of the other, it is essential in these cases that the apparently shortened limb should be compensated for. A purely functional tilting of the pelvis should never be compensated for, unless owing to lack of satisfactory treatment in its early stages a fixed deformity with scoliosis has finally resulted.

True shortening occurs most frequently after fracture of the femur, unreduced dislocation of the hip, osteo-arthritis, and certain diseases of the hip-joint; also in fractures of the leg below the knee. In children one of the commonest causes of shortening is anterior poliomyelitis.

In ordering a cork insole or so-called cork raising, provided there is useful range of movement in hip, knee, and ankle, one can order the full amount of raising up to 2 inches. Beyond this one can leave ½ inch or a little more for the patient's power of accommodation without risk of serious spinal deformity. Shortening of less than ½ inch may ordinarily be left alone. In all raised boots it is usual to graduate the cork insole from the heel forwards, allowing a drop of from ¾ inch or more between the heel and the tread, and in front of this the cork is fashioned so as to give a roll gradually decreasing in thickness up to the toes. This makes for ease in walking, and assists the toe of the boot to escape dragging on the ground.

In cases of shortening with stiff knee (ankylosis, or where there is range of flexion of less than 35°), in order to prevent the toe of the boot catching the ground in walking, it is necessary to give at least ½ to ¾ inch less raising than the actual shortening would otherwise require. A stiff knee with no shortening may actually require a raising of ½ inch on the sound side to permit satisfactory clearance in walking.

In hyper-extension of the knee (where knee can be flexed to more than 35°) it is wise to raise the heel about ½ inch more than the actual requirements of the shortening. This assists in preventing the knee from over-extending in walking.

The question of the graduation or gradual diminishing of the cork raising from heel to toe is subject to variation in special cases, depending on the integrity of the ankle-joint, and on the condition of the dorsiflexors of the foot. In cases of much shortening it may be found advantageous both as regards weight and appearance of the boot to make the graduation sharper than usual, so that a position approaching equinus may be obtained. It has to be remembered that the patient is going to wear the boot, and his preferences have to be always considered whenever they do not conflict with actual surgical necessity. "It is sometimes necessary to fit the patient's head as well as his foot."

Flat-foot.

In attempting to explain the surgical-boot requirements which this deformity necessitates, one is at first somewhat dismayed by the seeming complexity of the subject. The conditions are simplified, however, if we adopt the definition of Sir Robert Jones,[1] who states:—

> "Impairments of the longitudinal arch are associated with a train of symptoms which are found in the various degrees of weak foot, everted foot, and flat-foot. The term flat-foot may be taken as a generic name to include all degrees of strain of the longitudinal arch of the foot. To these varying conditions different names have been given."

It is well to keep clearly in mind that whether we are dealing with flat-foot or with other deformity of the foot, it is the last stage, the obvious osseous flat-foot (which no one could miss), which rarely requires any very definite surgical attention. It is essentially the early painful conditions of foot disability for which much can be done, and in these cases little or no deformity is to be seen. It is mainly by the situation of the pain and tenderness that we make our diagnosis. A normally high arch giving way may cause more discomfort than the most pronounced flat-foot.

The essential surgical alteration to boots, as pointed out by Thomas,[2] is the crooking of the heel on the inner side; this procedure has been previously explained. It was introduced by him originally for fractures about the ankle, to correct the splay-foot deformity which so frequently followed. Subsequently he used it for the flat-foot with necessary modifications, and it is possibly now the most universally known and adopted of all surgical alterations to boots. In the words of Thomas, its beneficial action arises not from bolstering up the arch of the foot, but by giving the foot an inward rotation. If all shoes or boots were made with a slightly crooked or oblique heel much foot trouble might be avoided. For young children especially such a modification of the ordinary shoe, combined with care and attention to the fitting round the heel, would be a decided advance towards prevention of flat-feet.

[2] Thomas, Owen: Contributions to Surgery and Medicine. London: H. K. Lewis. 1883–1890. Parts I.–VIII.

For prevention, restoration, or relief of variations from the normal symmetry of the inner longitudinal arch more can be done by specially modelling the heel and sole of the boot than by any other means. Money can be wasted on quack remedial measures, but the key of the situation is the crooked heel. In slight early cases of flat-foot the crooked and elongated heel may be sufficient. With varying degrees of severity the wedged sole patch on the inner side may be added, the turned-up insole faced with rubber, the special Thomas heel filling up the instep and "extending nearly but not quite to the ball of the big toe." A further modification is to prolong the normal stiffener of the heel upwards and inwards. In very severe cases of flat-foot in comparatively young and active persons, often due to trauma, it may be necessary to alter the heel of the boot to take an outside surgical iron with an inside T-strap, as well as to crook the heel.

In old people, and also when the deformity has become osseous, the surgeon's object is simply to fit the deformity, and to give comfort more than to attempt correction or cure. In the latter type of case the last on which the boots are made should be fitted up on the under side to correspond as nearly as possible to the shape of the sole of the foot. The heel should be rather low, well elongated and wedged with some inside stiffening. It must be carefully borne in mind that patients are not always going to find a marked surgical alteration to their boot immediately comfortable; they should be instructed not to attempt too much at first, and to persevere with what may seem at the outset to be an awkward addition to the boot.

Especially with women accustomed to high heels is it advisable to go to work very cautiously when lowering the heels or crooking them, and the alteration should be small at first, and gradually increased. Every case of flat-foot must be considered on its merits, and both the causative factor and the degree carefully investigated, otherwise the routine ordering of "crooked heels" may not always produce the desired effect.

Repairs.—The question of repairs to surgical boots is most important, and especially so with regard to boots for flat-feet. The whole desired effect of the boots may be negatived if repairs are not done early enough, or if they are not done by a surgical bootmaker who understands the requirements. A very pernicious practice is to put movable, round rubber heels on to a crooked heel; this completely destroys its efficiency.

Surgical bootmakers are by no means easy to convince, and Thomas states he had 24 years' wrangling with St. Crispin's fraternity. Explicit instructions must be given, and it is always wise to inspect the finished article to see that the instructions have been satisfactorily carried out.

Here the anterior arch of the foot is found to have flattened or even to have become convex on the plantar surface. Great relief is usually given by having a metatarsal bar added to the boot. Care must be taken to see that the bar is applied so that it comes behind the heads of the metatarsals and not under them. In many cases the metatarsal sock or pad referred to previously is very satisfactory, its action being to assist in restoring the anterior arch. As a preliminary to ordering this, it is useful to cut a small pad of felt ($\frac{1}{4}$ inch thick) to the required shape to fit behind the heads of the second, third, and fourth metatarsals, fix it in position by a piece of strapping round the foot, and let the patient wear this for a few days. In addition to the metatarsal bar it is usually advisable to crook the heel, making the inner side $\frac{1}{8}$ inch higher than the outer.

Metatarsalgia: Other Conditions Requiring Surgical Boots.

The following notes may help practitioners in ordering surgical boots suitable for the following conditions:—

Partial amputation of foot.—Surgical boot made to measurement of deformity; front of boot blocked with cork faced with sponge rubber; steel plate to be let into the sole of the boot to avoid buckling of the boot at the site of amputation.

Syme's amputation.—Special boot 3–4 inches higher than normal in the upper, to give support and to hide the deformity.

Pes cavus.—If not severe enough to require operative procedures, boots to fit the deformity, heels somewhat lower than normal, front of upper well raised to avoid prominent toes, and a metatarsal bar. Curative procedures by means of boots not very satisfactory.

Drop-foot.—Simple permanent drop-foot due to external popliteal nerve injury or infantile paralysis can be corrected to enable the foot to clear the ground. This can be accomplished by means of a jointed iron with box-socket fixed into the heel of the boot, and some form of drop-foot spring attached. The boot heel requires to be well built and strong to support the pressure. A T-shaped ankle-strap, as already described, is necessary, to be attached to the boot on the opposite side to the iron. Minor degrees of drop-foot may be assisted by a drop-foot tongue fixed to the front of the boot and buckled round the upper ankle: the boot should also be well stiffened to give support. In order to assist the patient in getting his foot in and out of the boot, it is advisable to have the boot laced low, either to the toe-cap, or no toe-cap ordered, and the boot laced to the toes. A boot with Derby front is most suitable for this type of case.

Hallux valgus and rigidus.—These deformities require boots of as soft a material as possible; a concealed metatarsal bar tapering to the outer side should be ordered, the heel should be crooked on the inner side as for flat-feet, with which these conditions are usually associated; and the inner border of the boot should be straight to allow the big toe to be drawn inwards towards the middle line of the body.

Hammer-toes.—Boots should be broad at toes and well raised in front to avoid any pressure on the prominent toes—metatarsal bar added.

Pott's fracture with eversion deformity of the foot, and fracture deformity of the foot itself with eversion.—In these cases it is advisable to strengthen the heel of the boot, add a round socket on the outer side and an inside T-strap, and to supply also an outside surgical iron fitting round the upper third of the leg. In addition, it is advisable to crook the heel of the boot on the inner side.

Painful conditions in the neighbourhood of the heel.—These may be temporarily relieved by placing a cork pad in the heel of the boot inside raised $\frac{1}{2}$ to $\frac{3}{4}$ inch and well padded with sponge rubber; this may take some of the pressure off the heel and relax the tendo Achillis, if its insertion should be the seat of bursitis, &c.

In extensive paralytic and congenital deformities it is often necessary, especially in female patients, to conceal the deformity wherever possible, and this may be done by attaching the steels, &c., which have to be worn to a leather support inside and not outside the boot. It is not maintained that the surgical alterations above listed exhaust by any means the possibilities in this respect; each deformed foot has to be treated as a separate entity, and much is left to the individual ingenuity of the surgeon and the surgical bootmaker.

Below is a typical order for a boot for, say, a case of old infantile paralysis of right leg with a short leg, and drop-foot with eversion and flat-foot.

Right boot, with cork insole raised 1 inch at heel, $\frac{1}{4}$ inch at tread, rolled to the toe, to lace to cap. Crooked and elongated heel, outside box-socket, inside T-strap, and fellow boot.

Outside iron for right leg, hinged ankle, and toe-raising spring.

In conclusion, we beg to thank the Ministry of Pensions for their kind permission to publish this article; also Mr. Bird, of Messrs. Beckett and Bird, New Cavendish-street, for his practical assistance in the preparation of the drawings.

PATENT MEDICINE ADVERTISING:

DOES IT NEED CLEANING UP, AND, IF SO, HOW CAN IT BE DONE?

AT a meeting of the Publicity Club, London, held at the Hotel Cecil on Nov. 17th, with Mr. WILLIAM YOUNG in the chair, a discussion was held on this question.

The Outsider's View.

Mr. GILBERT RUSSELL said that the Publicity Club wished not to attack patent medicine advertising, but to discuss the whole question. His remarks would represent his personal opinion, not an official statement of the club. Advertisements of patent medicines could be divided into two classes—the unobjectionable type making only reasonable claims which were justified by the drugs concerned, and the undesirable type which made exaggerated or even fraudulent claims. These could be found in plenty in any weekly religious paper. A typical example was the McQuorah vibrator which was advertised some years ago to cure most diseases. The proprietor had been hounded out of America, but was estimated to have made £60,000 in this country after an extensive advertising campaign. He then attempted to repeat the process in France, but was fined £120 and imprisoned for three years. Other examples could be found in the Report of the Select Committee of the House of Commons on Patent Medicine Advertising (1914). Their criticism of many medicines still being advertised was so drastic that Mr. Russell did not dare to repeat it. Again, a well-known antibilious remedy had been described by an Edinburgh judge as "a gigantic and too successful fraud."

The most disreputable class of patent medicine proprietor often traded under many aliases. The notorious Crippen, for instance, had been aural surgeon to the Droué Institute and was also known as M. Frankel. A most undesirable practice, which the Committee had recommended should be made illegal, was the advertisement of drugs as cures for diseases such as cancer, consumption, epilepsy, &c., which were known to be incurable by drugs. Mr. Russell quoted several advertisements of this class. Such advertisements were in no way exceptional and did much harm to the whole profession of advertising. Every lie harmed the honest advertiser, and owing to the exaggeration and frauds of patent medicine advertisers a growing section of the public was refusing to believe any advertisements at all.

The Select Committee's report had been a most devastating exposure of the subject, but had shown that there was at present no legal remedy. They had recommended that it should be made a breach of the law to give a false or misleading trade description of any remedy, and further, that patent medicine proprietors should be obliged to lodge with the Ministry of Health the formula of every remedy. It would thus become the duty of the Ministry of Health to watch patent medicine advertising and to prosecute when necessary.

Mr. Russell said that with regard to the deposition of their formulæ many manufacturers would probably object, but he did not see any real reason against it, since the Ministry of Health could be trusted as much as the Patent Office. Indeed, in many foreign countries the deposition or publication of the formulæ of proprietary medicines was already demanded by law. The above was a legal remedy, but it might be better still if advertisers would themselves produce a remedy. At present it was too difficult for an advertisement manager to refuse undesirable advertisements, but if a censorship board, composed of advertisers and manufacturers were formed to decide on a list of such advertisements as they considered objectionable, the difficulty would disappear, since managers could say they were not allowed to accept certain advertisements. Mr. Russell thought that such a board might succeed in spite of obvious difficulties. Some remedy was certainly needed, for while advertisements in general had undoubtedly been a social good, one exception must be admitted—namely, patent medicine advertisements.

The Medical View.

Dr. ALFRED COX (Medical Secretary, British Medical Association) said he would discuss the subject from three points of view—as a doctor, as a citizen, and as one who had to censor advertisements from the professional point of view. He considered the Select Committee's report on the subject the strongest House of Commons report he had ever seen, and was delighted with it. It should be remembered that the Committee was mainly composed of business men and newspaper proprietors. As a doctor he objected to patent medicine advertising because it was counter to the public interest. For instance, it involved long-distance diagnosis and treatment of disease by post. Every medical man would agree that this was impossible as disease was too complicated and variable. Again, owing to reliance on patent medicines patients sometimes postponed their application for proper treatment until too late, with disastrous results, as, for instance, in cancer or consumption. Dr. Cox then quoted from the Committee's report a number of most undesirable advertisements, including one well-known remedy whose proprietor had been arrested in America for fraud, and by pleading guilty of fraud had escaped with a fine. Another class of danger was illustrated by cough mixtures, which were advertised for all sorts of cough. Now some coughs were a symptom of irritation and needed soothing; others were a sign that secretion needed stimulation. It was impossible that one mixture should do both. A further evil was the constant stream of morbid suggestion in advertisements, which tended to make neurotic people regard drugs as a dope like alcohol which they could not do without.

Dr. Cox said he must emphasise the fact that doctors were not against patent medicines because they were injurious to the financial interests of doctors. On the contrary, doctors got much more out of patients who first tried patent medicines as cures than from patients who came straight to doctors. As a citizen he objected to the ridiculous claims of patent medicine advertisers and to their success, which was an indictment of the educational system of the country. Further, the fraudulent advertisers extracted most of their money from the poorest classes who could least afford it. As a censor of advertisements, he wished to point out how difficult it was to avoid being deceived. A frequent practice was to send papers respectable harmless advertisements of drugs which were sent out to purchasers with wrappers of the most exaggerated and fraudulent type. Any remarks he had made on the subject were very mild in comparison with some of the statements already published in the press. In support of this Dr. Cox read extracts from certain American newspapers which had decided to exclude all advertisements of patent medicines from their columns.

With regard to remedies, there were only two. First, the Select Committee's recommendations. These escaped publicity owing to their publication at the outbreak of the war. They had, however, been embodied in a Government Bill which had passed the House of Lords, but had later been withdrawn. Perhaps some Government would reintroduce such a Bill before long and would thus make the Ministry itself responsible for the question. The other remedy was for the advertising profession to clean up the matter itself. He would like to see this, and nothing would impress the public more favourably than such action.

The Manufacturer's View.

Mr. KENNINGHAM (Secretary to Association of British Proprietaries) said his Association stood for the more reputable class of proprietors, and was formed with the object of trying to clean up patent medicine advertising. Membership of the Association was confined to manufacturers who complied with certain regulations designed to exclude undesirable methods. He himself welcomed the Publicity Club's discussion, because if newspaper proprietors would see to the exclusion of the objectionable advertisements the matter would clean itself up without necessity for legal intervention. He did, however, object to Mr. Russell's remarks in that because of a few bad articles the whole trade was tarred with the same brush. Manufacturers, however, would not give their formulæ to a Government department. These formulæ were trade secrets, and fair play would not allow it. *Re* the Bill brought forward four years ago, Mr. Kenningham assured the meeting that this was not dropped owing to any request of the manufacturers themselves. The Bill would suit the manufacturers as well as the public. There was an enormous sale of patent medicines and there was no question that they did a great deal of good. Otherwise they would not sell as they did. Some patent medicines which had not been advertised for many years still had large sales simply because the public knew their value. All advertising men would agree that for an article to sell well it must be of good quality. In Great Britain about 100,000,000 packets of patent medicine were sold per annum, some two to three packets per person. In spite of all obstacles and criticisms, the sales of patent medicines continued to increase, largely because they supplied a real want on the part of the public. Doctors would freely generalise about the harm done by patent medicines, but he could not remember hearing any doctor quote a definite case of a patient who had been injured by them. He could not see why the reputable patent medicines should be classed in the same group with appliances and with the objectionable group. They were quite distinct, and it was not fair to class them together. His Association was perfectly willing to help to clean up the subject in any way possible, and they hoped the Bill would be passed. If any committee could be formed to exclude the disreputable advertisements from the newspapers the Association would be entirely in favour of it.

The Advertisement Manager's View.

Mr. **HORACE IMBER** said he was speaking from the advertisement directors' point of view. It was sometimes said that at least 30 per cent. of a doctor's cure was due to the personality of the doctor. In patent medicines this 30 per cent. was represented by the copy of the advertisement. As to the type of advertisements which should be accepted by a newspaper he had always made it a rule not to accept any advertisement of a disease which medical science could never cure—for instance, cancer and consumption. It had been his practice before accepting patent medicine advertisements to obtain a sample of the drug and have it analysed by a qualified chemist, but very few advertisements had been rejected as the result of such analyses. He considered the standard of advertising in this subject had been raised a great deal and in many cases was quite artistic. However, the other type of advertisement on which photographs of unpleasant people stared you in the face still sold the goods. Patent medicines, in his opinion, played a very important part in securing the health of the nation, because many people who were only slightly ill, and did not want to consult a doctor, would cure themselves by taking a patent medicine. A feature he did object to strongly was the inclusion of advertisements at the foot of the columns of reading matter at especially high rates. He would like nothing better than a committee which would help him in selecting reputable advertisements. His own medical knowledge was insufficient and he had to rely on the analyses of a qualified chemist.

An Advertiser's View.

Sir **WILLIAM VENO** said that if Mr. Kenningham's figure of 100 million packages was correct he manufactured 10 per cent. of it, and the sale was growing rapidly. While it was unpleasant to listen to some of Mr. Russell's drastic statements he entirely agreed with Dr. Cox's most reasonable remarks. He considered that manufacturers would lose nothing by exposing their formulæ if they were protected for them. Under such conditions he would willingly publish his own formulæ. He was very sorry that the Bill introduced four years ago had not become law. The manufacturers had studied it clause by clause and found nothing objectionable. They all agreed to it. He invited Dr. Cox to inspect his laboratories at Manchester, and would be delighted to show him everything. The alleged formula of Veno's cough cure had appeared in "Secret Remedies," but he had smiled when he saw it. It really contained six rather important ingredients. Three of these were grindelia, yerba santa, and balsam of tolu. In future advertisements these three ingredients would be mentioned, and if Dr. Cox knew of any more useful ingredient than these three he would be glad to put it in his cure. A good deal was said about the percentage of water in medicines, but in what else could the drugs be dissolved? If water was not used the medicines would be dangerously strong. The patent medicine business laid itself open to criticism because men with fraudulent intentions were attracted to it, but it was not fair to class all patent medicines together. There were two quite separate classes. The reputable medicines, such as Veno's cough cure (which could be bought for 1*s.* 3*d.*), were the poor man's medicine, and as such were really valuable. But the other class, the fraudulent medicines, should be cleared out of business altogether. One method of achieving this end would be to bring in legislation to set up a committee of doctors and chemists with power to visit laboratories. Legitimate businesses could then be registered and others stopped.

General Discussion.

Mr. **THOMSON WALKER** said Mr. Kenningham had referred mainly to reputable patent medicines, but we were not here to discuss the reputable ones. The objection to disclosing formulæ could not be so great as Mr. Kenningham had said, as was shown by Sir William Veno's readiness to disclose his formula to Dr. Cox, and by some advertisements. It was, however, an absolute necessity if the matter was to be cleaned up, and the patent medicine trade had brought the necessity on itself. Not merely bad patent medicines, but good medicines badly advertised must be considered. With regard to the precautions taken by some newspapers in excluding harmful advertisements these were necessarily inadequate. For instance, the guarantees of sending money back if readers were not satisfied, or the guarantee that remedies were not injurious were quite worthless. Some more drastic remedy was needed such as that proposed by Sir William Veno or by the Parliamentary Committee.

Mr. **STUART HIRST** (representing C. E. Fulford and Co.) said that the question of acceptance and rejection of advertisements was a very technical one. A recent widely accepted advertisement had shown how easily advertisement managers were deceived if sufficient skill was used in writing the "copy." In order to decide the question newspaper proprietors must have technical advice at their disposal. With reference to a previous speaker's criticisms of a certain advertisement, the formula published in "Secret Remedies" was incorrect, and the advertisement in question was correct in every respect. The case put by Mr. Russell only represented one side of a very complicated business. No campaign of calumny or misrepresentation would help, but only impartial study of this complicated subject.

Mr. **VALKENBERG** said that patent medicine advertisements did need cleaning up for the benefit of all other advertisers. The juxtaposition of advertisements of bad legs to costly advertisements of perfumery or similar goods was repellent and certainly harmful to the latter.

Mr. **B. W. ROWE** said that the fraudulent nature of many patent medicine advertisements discounted the public belief in other reputable advertisements, and so wasted millions of pounds annually in addition to that spent on the medicines themselves. He did not believe that an article in order to succeed must be a good article. In patent medicine advertising it would always be possible to fool the public and to make people believe they had been cured. In this subject the British love of freedom had gone too far, and the uneducated public must be protected from the fraudulent advertiser.

Mr. D. Mugford advocated the use of the term proprietary medicine instead of patent medicine, and quoted an advertisement of a well-known headache powder as misleading owing to the numerous possible causes of headache such as eyestrain. In the face of this and similar statements, there was real need for the publication of formulæ. The Bill relating to patent medicines was prepared as a direct result of the Select Committee's report, and in spite of his opposition to Governmental control in advertising he felt the Bill was a real necessity.

Mr. Kenningham said that a formula was the only protection for a trade-mark, and if once disclosed might lead to the loss of the trade-mark throughout the world. The position of a patent was quite different.

Reply and Resolution.

Mr. Russell replied to various criticisms and said that the meeting was not a campaign by the Publicity Club, but an impartial discussion by both sides.

Mr. Fleetwood Pritchard moved the following resolution :—

> That this meeting of the Publicity Club of London, held at the Hotel Cecil on Nov. 17th, 1924, representing the largest advertisement club in Great Britain, records its opinion that the present condition of the law in regard to patent medicine advertising calls for immediate reform, and urges the immediate introduction of legislation along the lines laid down by the Select Committee of the House of Commons in 1914.

The resolution was seconded by Mr. Rowe and carried unanimously.

SCHOOL MEDICAL SERVICE.

Aberdeen.

Dr. G. Rose, in presenting his fifteenth annual report, remarks that if the popularity of medical inspection is to be judged by the number of parents putting in an appearance at inspections, it is increasing in Aberdeen every year. Last year 70 per cent. of the parents were present, surely a record in any area. The Aberdeen school report nearly always presents us with a new point of view, and we deal with Dr. Rose's important investigation into the effect of rickets in infancy on the growth of the adolescent boy and girl in another part of this issue (see p. 1140). A policy of thoroughness is to be observed throughout the public health administration of the city. If one child of a family is found verminous, and the whole family is not cleaned within a certain time (and in this they get practical help in the way of instructions and disinfectants from the medical department), off they all go to the cleansing station, which they willingly do rather than face the publicity of a prosecution. The house then is thoroughly cleaned and disinfected ; fresh chaff is supplied for the beds, and where necessary the bed and body linen are washed as well as disinfected. The family thus get a fresh start in life, and seldom get into a like condition again. The scheme, which is unique, has worked smoothly since 1911, when it was inaugurated with considerable misgivings as to its success, which was assured largely by the tact of those dealing with the families concerned, and by the excellent provision for their comfort during the cleansing process. At the beginning the prosecution of a few cases of gross neglect and verminous conditions was necessary, but these have gradually become less frequent. Last year 99 families suffering from body vermin came under notice for the first time along with 54 families who had been under notice previously ; 66 of these families, including 174 adults, 100 schoolchildren, and 53 infants were treated at the cleansing station. The home accommodation amongst them was as follows : 24 had one room, 106 had two rooms, 47 had three rooms, 15 had four and five rooms. The figures speak for themselves. Casual and dock labourers contributed the largest number. The rearrangement of the clinical work, which has been made possible by provision of extra accommodation, has resulted in treatment being more expeditious and working conditions more comfortable. The clinics are central and therefore convenient for doctor and patient. The dental work, which is in the hands of one whole-time and one half-time dentist, assisted by a dental dresser who does temporary fillings and dressings, continues to increase in popularity. School hygiene as a whole will gain from this informative report.

Lindsey.

Lindsey has a school roll of over 39,000 children, of whom 12,345 were examined in the routine groups. Of these, over 15 per cent. required treatment, and approximately 20 per cent. needed further supervision. Including dental disease, which never fails to increase the numbers considerably, only 13·69 per cent. of the total number examined had no defect. Dr. R. Ashleigh Glegg prints seven separate rules for the preservation of children's sight, and it is to be hoped that they will circulate among the schools, for, as he points out, the chief cause of aggravation of defective sight is the failure of teachers to recognise the first principles of ocular hygiene. There is no doubt that if reading from books in school were definitely prohibited before 7 years of age, as would not be difficult now that an interest in hygiene generally has been stimulated among school teachers by school inspection, a diminution in the amount of visual defect would result. There are now 15 centres for the treatment of minor ailments. As a rule a doctor and a nurse attend once a week, but in a few of the smaller centres attendance is fortnightly, although in one district a nurse attends daily to carry out routine treatment. Operative treatment for enlarged tonsils and adenoids is given at certain hospitals and at the school clinic in Barton-on-Humber. Yet there still remained at the end of the year 1112 cases for which no treatment had been obtained. The head teacher's first annual report on the new Branston Hall Sanatorium is interesting enough to make one look forward to the second.

Nottinghamshire.

Dr. H. Handford has unfortunately had to retire on account of increasing ill-health, and Dr. T. E. Holmes acknowledges his indebtedness to the senior assistant medical officer, Dr. A. C. Tibbits, for writing the report. Although no new schemes have been inaugurated during the year, much solid groundwork has been accomplished. In spite of this the school dentist reports that the dentists were unable to complete the circuit of schools in the 12 months, and it is proposed to omit the reinspection of children who have twice refused treatment. The large number of refusals to accept dental treatment (60 to 70 per cent.) is an indication of the parent's own attitude, which is one of distrust and alarm, engendered probably by a mental association of dentists and painful extractions of badly decayed molars. A wholesale educational campaign on modified American lines, by means of attractive leaflets and lectures, is badly wanted in this particular direction ; so much depends on health efficiency, and so much of health efficiency depends on the state of the teeth. More and more the medical profession is realising that a healthy body only goes with a clean mouth. During the year 13,538 children were dealt with, 2628 of these being special cases. It is interesting to know that in Nottinghamshire the body-louse is " fast becoming extinct " ; this costly animal certainly ought to be disappearing ; in this county alone nine highly qualified school nurses made 131,466 examinations of children to ascertain their state of cleanliness. In the few districts where school clinics are available parents appear anxious to avail themselves of them, but many more are wanted. Railway journeys are difficult and expensive. A special plea is made for organised classes for dull and backward children, so many of whom profit by careful individual instruction impossible in the ordinary class; while a desirable addition to the staff would be an expert instructor in physical exercises. A teacher adequately trained in this direction ought to be found in every county to help and advise in the matter of graded physical training and of games, now playing such an important part in education. Twelve schools were closed on account of small-pox, and this epidemic, although fortunately a mild one, meant a considerable amount of extra work in the public health department.

Dover.

The school medical officer, Dr. A. B. McMaster, who is also medical officer of health, reports that over 2000 children were examined in 1923 in the routine age-group, and 14 per cent. of these were found to require treatment. Apart from dental defects, defective vision accounted for the greatest number. The incidence of defective vision was 7·6 per cent., which is low compared with other counties such as Kent and London. Fully a quarter of the special cases were presented on account of skin trouble of some description, mostly impetigo. Ringworm has diminished in the schools; there were 54 fewer cases this year than last, and 186 less than the year before. These children are treated by means of X rays. Altogether 752 children obtained treatment during the year, all under the authority's scheme, with the exception of 20.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. A. W. McRorie to be Surg. Lt.-Comdr.

R. G. Anthony to be Surg. Lt. for short service.

ROYAL ARMY MEDICAL CORPS COMMISSIONS.

An examination for not less than 20 commissions in the Royal Army Medical Corps will be held on Jan. 28th, 1925. Applications should be made to the Under-Secretary of State, the War Office, not later than Jan. 18th. Full particulars of the duties and emoluments of the service can be obtained on written application to the Under Secretary of State (A.M.D.1.), the War Office, Whitehall, London, S.W.

ROYAL ARMY MEDICAL CORPS.

Lt.-Cols. H. M. Morton (granted the rank of Col.) and A. D. Waring retire on ret. pay.

The undermentioned Majs. to be Lt.-Cols.: G. A. K. H. Reed, vice Lt.-Col. H. M. Morton; and Bt. Lt.-Col. J. M. H. Conway, vice Lt.-Col. A. D. Waring.

Capt. W. E. K. Coles relinquishes the temp. rank of Maj. on ceasing to be empld as a Dep. Asst. Dir. of Pathology.

REGULAR ARMY RESERVE OF OFFICERS.

Capt. W. S. Dawson, late R.A.M.C., Spec. Res., to be Lt.

Lt. C. C. H. Chavasse, from R.A.M.C., Reg. Army Res. of Off., to be Lt.

MILITIA.

Capt. A. D. d'Avray to be Maj.

TERRITORIAL ARMY.

Cadet D. Jack (Edinburgh University O.T.C.) be to Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Col. H. T. Challis having attained the age limit is ret. and retains the rank of Col. with permission to wear the prescribed uniform.

Lt.-Cols. T. Forrest, T. A. Green, and H. A. Rudyard having attained the age limit are ret. and retain the rank of Lt.-Col. with permission to wear the prescribed uniform.

INDIAN MEDICAL SERVICE.

The King has approved the promotion of Lt.-Col. F. H. G. Hutchinson to Col., and the retirement of Lt.-Col. G. A. Jolly. His Majesty has also approved the grant of a temporary commission to S. Mahmood Ali Khan.

LABORATORY CHANGES AT A HOSPITAL.

To the Editor of THE LANCET.

SIR,—I wish to support the protest, made in THE LANCET last week by Dr. Greenfield and others in their letter under this heading, against the proposed scheme for laboratory diagnosis advertised by the Hospital for Epilepsy and Paralysis, Maida Vale. It does not seem desirable that an institution depending on voluntary contributions from the public should compete at cut rates with the regular institutions carrying out clinical diagnosis commercially, and working pathologists would seem to have a real grievance here. The facts as to personnel being as stated, there are grave objections to the scheme. At the present time, when any unqualified person can claim to be an authority on medical subjects, it may seem hypercritical to object to pathological diagnosis being undertaken by those who have not gone through a probationary mill, and, as a matter of fact, no sensible person would object if this were a private commercial venture. The feature of the scheme to which exception must be taken is, that a medical institution should allow its reputation to be accepted as a guarantee that those who are to carry out the work are competent and qualified to a degree which justifies them in asking for the very moderate fees mentioned in the circular.

I am, Sir, yours faithfully,

J. A. MURRAY,
President, Pathological Section, Royal Society of Medicine.

London, Nov. 24th, 1924.

THE ALLEGED STERILITY OF PRESENT-DAY BACTERIOLOGY.

To the Editor of THE LANCET.

SIR,—The interesting letter of Prof. J. C. G. Ledingham on this subject in your issue of Nov. 22nd has probably raised some doubt in the minds of many thoughtful clinicians. Few will deny the soundness of Prof. Ledingham's contention that our knowledge of the ætiology of certain diseases such as syphilis, epidemic jaundice, and yellow fever has been greatly advanced in the last quarter of a century through the investigations of bacteriologists. It may also be fairly claimed that in regard to general medicine, in which the vast majority of practitioners are mainly interested, the period has been relatively sterile so far as results of value to practical medicine is concerned. I think, however, that in apportioning any blame for this state of affairs, it is hardly fair to blame the bacteriologists entirely. This should be divided at least equally between clinicians and bacteriologists. On the bacteriological side the period in question has not been entirely unproductive. It has produced a wealth of bacteriological technique and specialised knowledge regarding the life of bacteria, under the extremely limited conditions which come under the sphere of action and thought of the medical bacteriologist. It has further produced a wealth of classification which has done credit to the industry of bacteriologists, but a great deal more than this is required, and there is good reason for thinking that a change of outlook and practice is urgently called for if any real advance in the practical application of bacteriology to everyday medicine is to be made.

I can best illustrate my view by a reference to two points which have recently interested me as a clinician, with a keen interest in and an elementary knowledge of bacteriology.

1. In the last year or two, in connexion with certain practical problems of milk production and milk preservation, I have had occasion to make some simple bacteriological observations on milk, and, on seeking help from competent bacteriologists, I have been much impressed by their admitted lack of knowledge

and sometimes their apparent lack of interest in a question of such first-rate importance in general nutrition and medicine. The unfavourable results of excessive specialisation in the subject have been strikingly revealed.

2. I recently had occasion to make a simple bacteriological investigation of certain soils in order to test a theory that there may be close analogy between certain processes of nitrification and denitrification in the soil, and similar processes daily occurring in the human interior. In the course of these observations I obtained a bacterial culture from the soil, of an apparently pure organism, and experimented with it in the garden with results of an interesting and arresting kind. The organism in question had the typical morphological appearances and biochemical reactions of *Bacillus coli*. Here, again, a reference to several competent bacteriologists, both on the agricultural and medical side, failed to yield any helpful suggestions or criticism. The subject was obviously outwith their line of vision and their interest.

My experience has led me to the conclusion that while the training and outlook of bacteriologists and bacteriology teachers reflect the greatest credit on their work, from the limited point of view in which the subject is approached, a much wider outlook is essential if bacteriology is to advance our knowledge of general medicine in the next few decades. Medical bacteriology, like general medicine itself, is really a branch of biology, and until there is established an infinitely wider outlook and practice based on that wider outlook, the valuable secrets which could, in my view, beyond question be revealed by the skilled application of expert bacteriological knowledge to medicine, will remain secrets. For that reason one welcomes and endorses the statement in your leading article on this subject in the issue of Sept. 20th: "What there is most needed at the present time by all those who are engaged on the technological applications of bacteriology is the provision of facilities for teaching and research into how bacteria, irrespective of their human importance, live and move and have their being."

I am convinced that when the importance of this is realised and judiciously followed up by appropriate action, a step of vast importance to clinical medicine will have been taken; and, 10 or 20 years hence, there would be no justification for any letter appearing in your columns under the heading of "The Alleged Sterility of Present-day Bacteriology."

I am, Sir, yours faithfully,
CHALMERS WATSON, M.D.

Edinburgh, Nov. 24th, 1924.

To the Editor of THE LANCET.

SIR,—Prof. J. C. G. Ledingham has dealt with some asperity with certain observations on bacteriology that appeared in your issue of Nov. 15th; I would like to add a comment in somewhat lighter vein on the epithets that were applied to clinical pathology. Since reading your leading article and Prof. Boycott's address I have been greatly worried by the problem of my origin, and I would ask your help in deciding whether. assuming clinical pathology to be the mulish hybrid you suggest, it is by medicine out of pathology, or by pathology out of medicine; or, more bluntly, which of its parents is the ass? In asking this ticklish question I would not have it thought that I object to the epithets applied; on the contrary, I think them in many ways very apt. Your readers need no reminder that there is more than one story in the Scriptures that redounds to the credit of the ass, and mules at least give us a shining example of "the good life" which, as Prof. Boycott reminds us, is fulfilled by bearing other peoples' burdens. Throughout the long years since I was first Prof. Boycott's demonstrator I have owed him much more than he would permit me to tell; I wish I could feel worthy of this crowning gift, the halo of a saint. I am, Sir, yours faithfully,
G. W. GOODHART.

Warwick-gardens, Kensington, W., Nov. 24th, 1924.

PUERPERAL MORTALITY.

To the Editor of THE LANCET.

SIR,—In your issue of Nov. 15th, reporting the discussion at the Royal Society of Medicine on Puerperal Sepsis, Dr. R. A. Lyster is quoted as saying that the almost sole cause of maternal mortality was bad midwifery practice, the level of which could be raised by efficient supervision and inspection. Dr. Lyster does not, however, suggest how he would supervise and inspect the midwifery of the medical practitioner, but confines himself to adverse criticism of midwives' midwifery, making the startling statement that, by influence through their societies, midwives have prevented their work being properly checked and supervised, with the result that the working of the Midwives Act has resulted in little or no improvement in maternal or infant mortality.

As the Midwives' Institute is (with one possible exception) the only midwives' society to which he can allude, we should be interested to know how we were able to exert such influence as to nullify both the Midwives Act and the Notification of Births Act, and to obtain the support of the Central Midwives Board in these reprehensible practices. The Midwives Act gives very considerable powers to the local supervising authorities of the county or county borough. Dr. Lyster is the executive officer for his local supervising authority, and we ask him why his inspectors do not properly check and supervise the midwives of the county of Hampshire. Perhaps the midwives' societies have been active there also?

In regard to his "striking fact that the death-rate of infants during the first few days is comparatively high, and does not tend to diminish," we would remind Dr. Lyster of what we feel sure he must often have heard—viz., that the causes of the high neonatal mortality are chiefly pre-maturity, birth injuries, and maternal intoxication. We fail to see what effect on this mortality "the official visit to the house" of a health visitor would have. Dr. Lyster's faith in the health visitor from the town-hall, and his dread of the midwife who bears the burden and heat of the day is pathetic. We midwives have for long studied this question of the prevention of maternal mortality very earnestly. We feel that the solution has not yet been found, and doubtless depends on more than one factor. In the practice of well-trained midwives, supervised and inspected by efficient inspectors who are at the same time friends and advisers, and with competent medical consultants in difficulties, the mortality where midwives are engaged to attend has almost reached an irreducible minimum. (In 1923 the mortality in 54,554 cases attended by the nurse-midwives of the Q.V.J.I.N. was 1·4 per 1000, including every case in which medical aid was summoned.)

The Midwives' Institute feels greatly the importance of prevention; towards this the first step should be to find out the cause of every death in childbirth. This will not be achieved until there is in every case a post-mortem examination made by an independent medical official.

We consider, therefore, that the first steps in this matter should be: (1) A post-mortem examination on all deaths in childbirth. (2) A space on the notification of births card for the name and description of the person actually delivering the woman. (3) It should be made a penal offence for anyone not a doctor or a certified midwife to examine (p.v.) a pregnant or parturient woman. (4) That in every area there should be an obstetric consultant whom midwives could consult antenatally, at labour, and postnatally. (5) That in every area there should be beds where a midwife could send a bad emergency case, and a service of motor ambulances. (6) That certain elementary matters concerning the hygiene of marriage and motherhood should be taught to young men and women before marriage.—I am, Sir, yours faithfully,
E. SIMPSON,
Secretary, Midwives' Institute.

INTRA-OCULAR TENSION IN MYOPIA.

To the Editor of THE LANCET.

SIR,—Dr. Edridge-Green, writing on the above subject in your issue of Oct. 25th, states his belief that myopia is produced by dilatation of the eye through increased intra-ocular tension caused by back pressure through the veins of the eye, as the direct result of strain. The ordinary explanations of the occurrence of myopia—viz., that vigorous muscular action in the act of convergence, and pressure of the extra-ocular muscles, notably the internal rectus and superior oblique, exercising undue pressure on the eyeball, thereby cause a lengthening of its antero-posterior axis—are allowed to be very unsatisfactory. The shape of the eye depends chiefly on its firm resistant outer coat, which is formed by the strong opaque sclera, supported in the posterior two-thirds of the eye-ball by the capsule of Tenon, with the cornea in front. The cornea and the front part of the sclerotic are supported by the lens with ts capsule and ligament. In health, the fundus and the sides of the eyeball are well braced up by the extra-ocular muscles as a whole, and the fundus is supported by the fat and areolar tissue which lies between it and the orbit. Myopia is essentially associated with debilitated states of the individual and s a disease of modern civilisation. The condition is seldom congenital, but tends to develop between the ages of from 4 to 16 years, most commonly about the period of adolescence. During wasting illnesses it is apt to increase and it may diminish as health and vigour return. In other words, it is associated with a marked endency to debility rather than to continuous and excessive muscular action.

Normally, the sclerotic coat is thinner in the young child than in the adult; and in rickets, and other debilitating diseases, notably after measles and whooping-cough, it tends to be softened and is still more attenuated as a result of malnutrition. Rickets plays a formidable part in the production of these debilitated states, and, like scoliosis, flat-foot, and knock-knee, myopia may arise as the sequel of the persistence of a debilitated muscular state long after he active disease has subsided. In other words, diminished resistance of supporting structures rather han increased strain is, I believe, the essential actor in the production of myopia.

I am, Sir, yours faithfully,

J. LAWSON DICK.

Cholmeley Park, Highgate, Nov. 23rd, 1924.

THE THERAPEUTIC VALUE OF MUSIC.

To the Editor of THE LANCET.

SIR,—During a vast personal experience of music nd musicians, contentment among listeners has, think, been the dominant outcome of any well-rdered musical effort. Excitement, never immoderate, s common enough and mostly pleasurable, and once n a way overwhelming sadness; but music has lways seemed to me less objective in itself than suffusing influence pervading receptive ground, wakening latent mentality, invaluable in cerebral atigue or torpor, often soothing, more sedative, nd, in my own person, an unfailing incentive to ntellectual effort in cloudy moments.

We may certainly associate soft music with the ulling or obliteration of pain for a while, and there is, erhaps, an association of harmony in sound with the roduction of hypnotic anæsthesia by other means, hough what refinements of molecular change underlie n the sensorium the abeyance of mental activity e know not. There is, moreover, a close resemblance n physiological action between music and other timuli which regulate the vaso-motor activity oncerned in tissue change and glandular function, ut we cannot measure the administration of music n terms of drug value or dosage.

Further than this I am not prepared to go, and I have little hope that music as a therapeutic agent will respond to the extravagant expectations now in vogue. The best effects are far too transient to be of substantial value even in functional derangement, and we surely need not expect success in the presence of organic lesion. The malady of Saul baffled David, but the cerebral apathy of Elisha yielded to the effective harmony of the Minstrel. There are, besides, certain mental extremities in which, as with Darius the King, music is simply intolerable. Truly, Music was the earliest and most spontaneous of the Arts, and if regarded as a language she speaks in a perfect babel of dialects to suit her listeners.

In early days I was bassoon in a quartet composed of oboe, cor anglais, tenoroon and fagotto, and we were the accepted exponents both in theory and practice of orchestral double-reed instruments. We played the organ fugues of Bach and Handel with other sane music. M. Costa listened to us with sparkling approval; Grove came for information for his Dictionary, and Haweis to talk. We played everywhere, not infrequently in some of the lunatic asylums, at Earlswood especially, with the control of epilepsy in view. But no good came of this and we seemed among the epileptics to be confronted with a depressing and impenetrable vacancy. We never adopted the fanciful interpretation suggested by emotional listeners, but gladly accepted the *deductio ad absurdum* of the American who claimed our sympathy in an attack of hay fever contracted during a recital of the Pastoral symphony with its cuckoos, quails, and other vernal influences. In my pre-Troyte days I took many a bell in steeple change-ringing and used to compare the melodious intricacy of Stedman's doubles with some of Bach's best work. But music as a separate entity never diverted us from the graver avocations of medicine and science, nor have I followed the descent of harmony to the ministration of fox-trot and bunny-hug displays. Sir Walford Davies would hardly be concerned to explore the language of music in such association. The ladies of the Prophet Ezekiel would be more worthy exponents. I am, Sir, yours faithfully,

MICHAEL GRABHAM, M.D., LL.D., F.R.C.P.

Madeira, Nov. 19th, 1924.

METASTATIC GAS GANGRENE.

To the Editor of THE LANCET.

SIR,—All surgeons engaged in gastro-intestinal surgery will sympathise with Mr. B. T. Rose in the loss of a patient from this very rare complication after gastro-enterostomy (see THE LANCET, Oct. 4th, p. 726). But, in addition to the interesting problem as to the origin of this virulent infection, there is, I think, in this case a point of technique possibly of some importance. The posterior operation, generally so easy, was performed, Mr. Rose reports, "with some difficulty as the omenta were very fatty and the stomach small and high up."

I venture to suggest that under such circumstances the anterior operation would have been preferable. Curiously enough I have just operated on a patient whose lesions resembled those recorded in this case. A very fat man, aged 30, had a grossly diseased appendix and a well-marked duodenal ulcer in a stomach without any dilatation. After appendicectomy, on turning up the colon loaded with fat, I found the mesocolon consisted of a sheet of thick fat in which one small vein was faintly visible. Without hesitation I performed the anterior operation and entero-anastomosis.

My experience leads me to perform it in three different conditions of the mesocolon: (1) If it be excessively fat; or (2) abnormally vascular, so that an adequate opening cannot be made without troublesome bleeding; or (3) so short that the colon would be anchored too near the anastomosis. If fat be present to a considerable but not excessive extent in a sufficiently lax mesocolon, W. J. Mayo's well-known method of dealing with it should be employed; the edges of the mesocolic opening should not be sutured to the jejunum, but away from the suture line well up on the stomach cone.

The immediate and remote results of the anterior operation have been excellent, as satisfactory as the posterior, with perhaps the disadvantage of a slightly higher liability to subsequent ulceration of the anastomosis. But if this troublesome complication occurs, the secondary gastrectomy required for its relief is, of course, much easier than when the short loop posterior operation has been performed. The value of the anterior operation in selected cases has been insisted on by several surgeons, and quite recently again by Balfour,[1] who writes of it: "Anterior gastro-enterostomy, particularly when combined with entero-anastomosis, is a more useful substitute for posterior gastro-enterostomy than is generally believed."—I am, Sir, yours faithfully,

Huelva, Spain, Nov. 10th, 1924. IAN MACDONALD.

BACTERIOLOGY AS A DEGREE SUBJECT.

To the Editor of THE LANCET.

SIR,—In his address on the Progress of Pathology Prof. A. E. Boycott seems to imply that Cambridge, Manchester, and Leeds are making new departures by admitting pathology and bacteriology as subjects for science degrees (your issue of Nov. 15th, p. 999). May I remind Dr. Boycott that the University of London, in which he is a professor, for years has allowed bacteriology as a subject for the B.Sc. degree, and that pathological and bacteriological subjects may be presented for the M.Sc. and Ph.D. degrees since these were instituted.

I am, Sir, yours faithfully,
R. TANNER HEWLETT.

University of London, King's College, Nov. 24th, 1924.

MEDICAL SUBSCRIPTIONS AND INCOME-TAX RETURNS.

To the Editor of THE LANCET.

SIR,—At the last meeting of the Council of the Medical Defence Union a letter was received from the Board of Inland Revenue stating that the Board will offer no objection to the allowance of the annual subscriptions to the Union as an expense in the computation of the professional profits for income-tax purposes of members who are assessable under Schedule D of the Income Tax Act, 1918.

I am, Sir, yours faithfully,
JAMES NEAL,
General Secretary, Medical Defence Union.

49, Bedford-square, London, W.C. 1,
Nov. 21st, 1924.

PROPHYLACTIC QUININE IN INFLUENZA.

To the Editor of THE LANCET.

SIR,—Dr. Wishart's remarks last week on quinine in erysipelas recall the report on quinine as a prophylactic in influenza made by Generaloberärzt H. Kayser,[2] who found, in 1918, that 0·3 g. (5 gr.) every two or three days prevented an attack or secured that the attack should be slight, and that the same dose, given twice or oftener daily, protected patients from the dreaded lung infections. He further added that influenza first attacked his division on May 26th, 1918, when they were in damp, non-ventilated catacombs at Montdidier; their number of cases per 1000 per month were: May, 24; June, 20·7; July, 65·6; August, 4·7. There were fewer cases in the October pandemic, which relief he ascribed to quinine prophylaxis. The official British view seems to be [3] that quinine and salicylates were of little use.

I am, Sir, yours faithfully,
Nov. 24th, 1924. M.D., B.Sc.

THE GENERAL MEDICAL COUNCIL.

PRESIDENT'S ADDRESS.

THE winter session of the General Medical Council was opened on Nov. 25th, Sir DONALD MACALISTER presiding.

The President began by expressing regret that two much esteemed members of the Council had been removed by death. He said: "Lieut.-Col. Benjamin B. Connolly, C.B., of the Society of Apothecaries, after a long and honourable career in the military service of the Crown, became our kindly colleague and friend six years ago. Sir Sydney Russell-Wells, of the University of London, who joined the Council at the same time, and was from the outset eager to take part in its activities, was suddenly and untimely cut off in the full tide of his Parliamentary, academic, and professional life. Another eminent colleague, Dr. Matthew Hay, of the University of Aberdeen, who became a member in 1919, has resigned, I am sorry to say, largely on the ground of health. His professional distinction as a leader in sanitary science and preventive medicine added greatly to the repute of the Council, and in particular of its Public Health Committee. It is fortunate that we were able to profit by his enlightened coöperation in framing the improved rules for diplomas in public health, which the Council at the instance of that Committee has recently promulgated. We trust that freedom from some of his onerous official duties may conduce to his recovery. Prof. W. H. Gilmour, appointed in 1921 by the Privy Council as an additional member under the Dentists Act of that year, retires on ceasing to be a member of the first Dental Board. His experience in questions of dental education enabled him to contribute effectively to the working out of the new dental curriculum. If circumstances should hereafter admit of his return to office, the Council will be glad to welcome him back again.

New Members.

"Meanwhile, it will be your pleasure to welcome the new members who join us this session to carry on the work of the old. Mr. Samuel Osborn, representing the Society of Apothecaries, is a worthy representative also of the Red Cross, under which he has won high honours in many lands. Prof. Ashley Watson Mackintosh holds the Regius Chair of Medicine in Aberdeen, formerly occupied by our late colleague, Dr. David Finlay, and therein maintains the fine traditions of the northern school. The University of London sends us Dr. Herbert Lightfoot Eason, C.B., C.M.G., superintendent and senior ophthalmic surgeon of Guy's Hospital, whose knowledge of his special branch of surgery will, I doubt not, be drawn upon by the Council when matters relating to the medical curriculum and its limitations are in hand. The new additional member appointed by the Privy Council under the Dentists Act, 1921, is Mr. William Robert Ackland, who has lately been elected to the Dental Board. We shall hope to make his acquaintance during this session. The election of six Direct Representatives, to take office as from Jan. 1st, 1925, has been held during the present month. I am not yet officially apprised of the results, except those for Scotland and Ireland. There it is known that our old friends, Sir Norman Walker and Dr. Leonard Kidd, have been elected without opposition, and we may therefore still count (accidents apart) on finding them in their accustomed places next year. Of the four remaining members it would not become me, as returning officer, to go beyond an expression of satisfaction that they remain with us till the end of this year, at least. We shall learn more regarding the future Direct Representatives when we receive the return of the English Branch Council this afternoon.

The Irish Free State.

"The position as regards the Irish Free State is not yet authoritatively determined. Legislation, which was deemed necessary to remove doubts and to establish an explicit basis for complementary Government action in this country, has been initiated in the Irish Parliament, but it has not yet been carried through its final stages. Pending the completion of such legislation, the Irish Government asked in August last for an assurance that the position, as regards the General Medical Council, would 'continue unchanged for the present.' Acting on the advice of the Executive Committee, which had considered the general question on July 28th, I forwarded to the Lord President, for communication to the Free State Government through the Colonial Office, an assurance that 'all procedure respecting elections, registration of students and practitioners, &c., shall continue, until the meeting of the General Council in November next, as if the Medical Acts were in undisputed force and effect in the Free State.' This assurance has been duly implemented by me, on the authority of the Executive Committee; but it will now fall to the Council itself to consider the question, after receiving in camera such information on the subject as is at present at my disposal.

Reciprocity.

"As I reported to you in my last address, the Executive Committee have been conducting negotiations, through the Privy Council and the Foreign Office, with the Italian Government on the question of reciprocity with this country. By the operation of a recent Italian law the privilege of practising in Italy, hitherto accorded to British practitioners, has been practically abrogated, while the privileges accorded by this country to Italian practitioners remain intact. Considerable delay, apparently due to departmental difficulties, has arisen in the conclusion of a 'special agreement' which would have the effect of restoring normal reciprocal relations. We have now been notified that an assurance has been given to the British Ambassador, by the Acting Director-General of Political Affairs at the Italian Foreign Ministry, that the difficulties in question have been surmounted, that the general tenor of the 'special agreement' is approved, and that an official reply in that sense may be expected at an early date. We are informed that a considerable number of British practitioners are in the meantime detrimentally affected by the existing restrictions, and if a remedy is not speedily provided it will be the duty of the Executive Committee to propose to the Lord President of the Privy Council that steps should be taken to determine the application to Italy of Part II. of the Medical Act, 1886.

"A similar position has arisen in the Canadian Province of Saskatchewan, with which we have hitherto been in relations of reciprocity. A local law has been passed, apparently in ignorance of its sweeping effect, restricting provincial registration to British practitioners who are 'duly registered by the General Medical Council of Great Britain after examination by the said Council.' As the Council does not itself examine applicants for registration here, this provision excludes from provincial registration all who are henceforth admitted to our Register, and thereby abolishes reciprocal recognition. Inasmuch as practitioners licensed after examination by the provincial authorities still continue to be registrable in this country, it is clear that either the new provincial law must be amended, or the privilege extended to the Province of Saskatchewan must be discontinued. The position has been clearly explained to the local authorities and to the Dominion Medical Council, and the Executive Committee will await their considered replies, and also that of the New Brunswick Council, which has proposed a somewhat similar restriction on reciprocity, before making formal representations to the Privy Council on the subject.

Medical Degrees of Indian Universities.

"The Executive Committee at the May session considered the reports on the course of study and examinations for the medical degrees of four Indian universities furnished by Colonel Needham, the official inspector appointed by the Indian Government and approved by the Council. In the case of two universities, the Punjab and Calcutta, it was agreed that, on the fulfilment of certain conditions, the recognition by this Council of the M.B., B.S. degree for registration in this country, which is required under Section 13 of the Medical Act, 1886, should be continued till Nov. 30th, 1924. The inspector reports that the conditions are in course of being fulfilled by the Punjab University, and the Committee has resolved to continue recognition of its degrees, under the same conditions, till Nov. 30th, 1925.

"The University of Calcutta would appear to be indifferent to the recognition of its degrees as qualifications registrable in the British Register, for it has not seen its way to fulfil the conditions accepted by the other Indian universities; nor has it, as they have done, afforded the inspector the facilities necessary to enable him to report on the methods and standards it adopts in respect of the final examinations in medicine, surgery, and midwifery. Accordingly, in the absence of the data required to justify the Council in continuing to offer the guarantee laid down in the Medical Act, 1886, the recognition of Calcutta degrees in medicine and surgery will automatically lapse on Nov. 30th. Degrees granted by the Univesity of Calcutta after that date will not confer a title to registration qualifying for practice in the United Kingdom.

Advertising.

"The publication of the Council's Warning Notice on the subject of advertising has been followed by a number of communications, many of them anonymous or 'confidential,' calling attention to alleged infractions of the notice. These communications are, as a rule, unaccompanied by any evidence that the alleged 'advertisement' was directly or indirectly procured, sanctioned, or acquiesced in by the medical practitioner concerned. In some cases the 'advertisement' has been indignantly disclaimed and repudiated by the practitioner named therein, by letters addressed to the Council and to the persons responsible for its publication. It should be understood by the profession and the public that the Council, as a judicial body, cannot institute an inquiry into the conduct of a practitioner unless some substantial prima facie evidence implicating him is submitted for its consideration. Vague charges, which the complainant cannot or will not support by any such evidence, must necessarily be ignored by the Council.

"Your time during this session will, as usual in November, be mainly occupied in considering cases of discipline, in which the Penal Cases Committee have found that evidence calling for inquiry, and for answer on the part of a practitioner, is forthcoming. To meet the convenience of the additional members of the Council, the dental business of the session will be taken on Friday of this week. So far as can be foreseen, that business may be completed in one day, and the session may accordingly end within the week."

A vote of thanks was moved to the President for his address by Sir JAMES HODSDON, and seconded by Sir NORMAN WALKER. The Council then debated the position as regards the Irish Free State in camera, and proceeded later to the consideration of penal cases, of which there are 13 down for hearing.

DENTAL BOARD OF THE UNITED KINGDOM.

THE concluding meeting of the seventh session of the Dental Board of the United Kingdom was held on Nov. 13th. Following upon the consideration of the penal cases (THE LANCET, Nov. 22nd, p. 1093), the reports of various committees were received. Under the Education Grants Committee certain detailed recommendations were adopted, the same course being followed under the Propaganda Committee.

Interim reports from workers investigating the causes of dental diseases, forwarded by the Medical Research Council for the information of the Board, were read and approved. A report of the solicitor, on the appeals to the High Court of Justice from the decisions of the Dental Board, was considered. Three appeals were dealt with, while a further appeal is pending.

Obituary.

CRESSWELL BURROWS, M.D. CAMB., M.R.C.S. ENG.

Dr. Cresswell Burrows, assistant medical officer of the Public Health Department of the London County Council, died at Cambridge on Nov. 13th at the age of 47. He took his B.A. at Cambridge University in 1896, and studied medicine in London at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1901. In 1910 he gained the M.D. Camb. Choosing to devote himself to the public health, he acted as resident medical officer at the Willesden Isolation Hospital and as assistant medical officer of the Metropolitan Asylums Board. In 1912 he was appointed assistant medical officer to the London County Council, and subsequently to that time, with the exception of his army service on the Western front during the war, he gave himself to the work of the school medical service in the East End of London. Immediately upon demobilisation he took up again his work in the London School Medical Service. A colleague writes of him : " Burrows preferred making his life work that of ameliorating the condition of the children in the East End of London rather than seeking a path in the profession which would lead to monetary advantage or renown. His quiet devotion to duty and his sterling integrity were a support and stimulus to his co-workers in the field he chose. He will be deeply mourned, not alone by his medical colleagues, but by a large circle of teachers, parents, and children in the London schools, who know and appreciate to the full his altruism and his self-sacrificing spirit."

MAURICE GILBERT HANNAY, M.D. BRUX., M.R.C.P. LOND., F.R.C.P. EDIN.

WITH the recent death of Dr. M. G. Hannay there has passed a promising dermatologist, who, though finding his métier rather late in his career, was rapidly securing recognition at the time of his premature death—for he was only 48 years old when a brief illness had a fatal issue. A student at Charing Cross Hospital, whence he qualified as M.R.C.S. Eng., taking also the M.D. Brux. with honours, he was for many years in general practice, but at the same time he worked regularly as clinical assistant in the Skin Department at Charing Cross. During ten years in this position he published notes in the dermatological papers under his own name or in association with the late Sir James Galloway, which showed grasp of many difficult clinical points; and as soon as the opportunity offered, he devoted his whole time to the subject, studying in Paris and Edinburgh as well as in London, and proceeding to the diplomas of M.R.C.P. Lond. and F.R.C.P. Edin.

During the war he saw service at the base hospitals in this country and later both in France and Germany, but at the conclusion of hostilities he settled down to his special line of practice in London, when he was elected honorary physician to St. John's Hospital for Diseases of the Skin, later becoming dean and lecturer at the London School of Dermatology. A personal friend writes : " Hannay's death will be keenly felt both by his patients past and present and by the professional colleagues with whom he had come into contact, for he was courteous, unselfish, and reliable, and always displayed the highest sense of duty."

FREDERICK JOHN PALEY, M.R.C.S. ENG., M.D. LOND.

THE medical profession in Hove and Brighton sustained a severe loss on Nov. 12th by the death from heart failure, following an operation for appendicitis, of Dr. F. J. Paley, surgeon to the Sussex County Hospital. He had been in practice in the twin towns for 34 years, and during that time rendered devoted services to many Catholic institutions, not only there but in the county of Sussex as well. Dr. Paley was born at Peterborough in 1859. He was educated at the Oratory School, Edgbaston, Birmingham, and he began his medical education at University College, London. He took the M.B. degree in 1883, and became L.R.C.P. and M.R.C.S. Eng. in the same year. For a short time he practised at Boscombe, Bournemouth, but afterwards went to Sussex as resident medical officer of St. George's Retreat, Burgess Hill. He proceeded to Brighton as house surgeon at the Royal Sussex County Hospital and afterwards held a number of other appointments. During this time he became recognised as a surgeon of unusual ability, and commencing in private practice in 1900 he had the honour that year of being elected President of the Brighton, Hove, and Sussex Medico-Chirurgical Society. Since 1907 he has been one of the hon. surgeons to the Royal Sussex County Hospital, Brighton. His personal qualities were most engaging. Striking alike physically and mentally, he was one to whom his colleagues could look for well-considered advice and guidance. During the war Dr. Paley was Commandant of the 2nd Eastern General Hospital at Brighton, holding the rank of lieutenant-colonel in the R.A.M.C. (T.F.).

Sincere sympathy will be extended to Mrs. Paley and other members of the family in their bereavement.

THE LATE DR. G. E. HASLIP.

IT has been pointed out to us that the wording of the obituary notice of Dr. G. E. Haslip in THE LANCET last week suggested that he was only chairman of the Medical Insurance Agency for the last two years of his life. Dr. Haslip was elected chairman of the Agency in succession to the late Dr. Henry Radcliffe Crocker in 1909, and during the whole period, including the last two years of his life, during much of which he was a serious invalid, he presided over the meetings. The cause of all the less prosperous members of the medical profession always lay near his heart, and his work as chairman of the M.I.A. for 15 years had its main stimulus in the fact that the prime object of the Agency was to earn for medical charities pecuniary support. During his chairmanship the Agency was able to devote to medical charities sums totalling over £12,250.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDING NOV. 15TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely : Small-pox, 51 ; scarlet fever, 2184 ; diphtheria, 1172 ; enteric fever, 69 ; pneumonia, 1013 ; puerperal fever, 55 ; cerebro-spinal fever, 6 ; acute poliomyelitis, 21 ; acute polio-encephalitis, 1 ; encephalitis lethargica, 31 ; dysentery, 10 ; ophthalmia neonatorum, 100. There were no cases of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 4 deaths from enteric fever, none from small-pox, 10 from scarlet fever, 45 from diphtheria, 35 from measles, 60 from influenza. In London itself the number of deaths from diphtheria was 17 and from influenza 15.

INSTITUTION OF SANITARY ENGINEERS. — A sessional meeting will be held at 7.30 P.M. on Wednesday, Dec. 3rd, at Caxton Hall, Westminster, S.W., at which a paper will be read by Mr. H. Alfred Roechling dealing with House Drainage, with Special Reference to the Intercepting Trap. A discussion will follow.

Medical News.

UNIVERSITY OF CAMBRIDGE.—The General Board of Studies have appointed Mr. W. A. F. Balfour Browne (Caius) as University Lecturer in Zoology.—The Diploma in Medical Radiology and Electrology is to be granted to Dr. J. M. W. Morison, of Glasgow University.

UNIVERSITY OF LONDON.—A meeting of the Senate was held on Nov. 19th, Prof. E. A. Gardner, the Vice-Chancellor, being in the chair.—Mr. F. L. Hopwood, D.Sc. Lond., was appointed to the University Chair of Physics tenable at St. Bartholomew's Hospital Medical College. He had a distinguished career as a student at University and King's Colleges, London. He was demonstrator in physics at the Royal College of Science from 1904–06, and since 1906 at St. Bartholomew's Hospital Medical College. He has also held teaching posts at Bedford College and University College among other institutions. During the war he was for three years a research physicist to the Admiralty and received the thanks of the Admiralty Submarine Department and an award of £1000 for his inventions used by the Service. —The title of Reader in Human Embryology in the University was conferred on Mr. R. J. Gladstone, M.D., C.M. Aberd., F.R.C.S. Eng., in respect of the post held by him at King's College. In 1895 he was appointed junior, and in 1896 senior demonstrator of anatomy at Middlesex Hospital Medical School, and from 1909–13 he was lecturer on embryology at the same school. Since 1913 he has been lecturer and senior demonstrator in anatomy at King's College. He has published a large number of papers in the *Journal of Anatomy and Physiology*, the *Journal of Anatomy*, and other scientific periodicals.—It was resolved to institute two University travelling scholarships, open to internal and external graduates in all faculties, each of the value of £275 per annum, and three University post-graduate studentships (open to internal and external graduates in the faculties of Theology, Arts, Laws, Music, and Engineering) of the value of £150 per annum.—Mr. G. V. Anrep, D.Sc., was awarded the William Julius Mickle Fellowship for 1925 in respect of the work which he has carried out during the past five years in experimental physiology. The Fellowship is of the value of £200.—Dr. H. L. Eason was appointed to represent the University on the General Medical Council.

At the recent examination for the *Diploma in Psychological Medicine* the following candidates satisfied the examiners: With special knowledge of psychiatry: William McWilliam and Thomas P. Rees. With special knowledge of mental deficiency: Geoffrey F. Cobb and Anne Fairweather.

Entrance Scholarships and Exhibitions in Medicine, 1925.—Thirteen medical entrance scholarships and exhibitions of an aggregate total value of £1473, tenable in the Faculty of Medical Sciences of University College and King's College, and in the medical schools of King's College Hospital, University College Hospital, the London Hospital, and the London (Royal Free Hospital) School of Medicine for Women, will be offered. The examinations for medical scholarships will commence on April 21st and June 30th, 1925. Full particulars and entry forms may be obtained from the Secretary of the Board, Mr. S. C. Ranner, M.A., the Medical School, King's College Hospital, Denmark Hill, London, S.E. 5.

A public lecture by Sir Gregory Foster on "The University of London, What It Is and What It May Be" has been arranged by the XXth Century Society of London Graduates. It will be delivered at the London School of Economics and Political Science, Kingsway, on Dec. 4th at 8.15 P.M. Admission is free.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—A. J. Fraser, Guy's Hosp.; L. Freeman, St. Thomas's Hosp.; C. H. Mason, St. Mary's Hosp.; K. Samaan, Manchester; Y. S. Wan, St. Bart.'s Hosp.; and H. Winstanley, Liverpool.

Medicine.—A. J. M. Davies, St. Mary's Hosp.; M. Murad, Birmingham; and Y. S. Wan, St. Bart.'s Hosp.

Forensic Medicine.—S. W. Cuff, St. Bart.'s Hosp.; L. Freeman, St. Thomas's Hosp.; Y. S. Wan, St. Bart.'s Hosp.; and D. Winstanley, Liverpool.

Midwifery.—C. L. Copeland, Univ. Coll. Hosp.; B. Davis, Bristol; J. Dywien, Guy's Hosp.; L. Freeman, St. Thomas's Hosp.; A. Kaplan and C. H. Mason, St. Mary's Hosp.; C. C. Taffs, St. Thomas's Hosp.; and Y. S. Wan, St. Bart.'s Hosp.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: A. J. Fraser and Y. S. Wan.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The annual meeting of the Fellows and Members of the College took place at Lincoln's Inn-fields on Nov. 20th. Some 70 persons were present when Sir John Bland-Sutton took his seat. Among the questions put by those present, Mr. C. E. Wallis asked whether the Council of the College had received any complaint with regard to advertising, direct or oblique, on the part of Fellows or Members, and if it was proposed to deal with the offenders under Rule 16 of the College. The view of the President was that in such cases the lead of the General Medical Council, which had the power to call witnesses, should be followed. Dr. W. E. A. Worley then moved: "That this thirty-sixth annual meeting of Fellows and Members again affirms the desirability of admitting Members to direct representation upon the Council of the College; moreover, this meeting requests that the President shall hereupon reply in detail to the two resolutions passed at the last annual meeting, and that he shall also state whether his Council has seriously considered any means whatever whereby the collective views of Members of the College may be ascertained on matters affecting their interests as Members." He said that a feeling of dissatisfaction justly existed amongst the Members at their exclusion from participation in College affairs. Dr. M. I. Finucane seconded the motion, stating that the experience of the Members was worth cultivating in such matters as the medical curriculum and the standards of examination, while the appointment by the Council of the representative of the College on the General Medical Council was a further illustration of an undemocratic system. Dr. Redmond Roche, President of the Society of Members, supported the motion, and made special reference to the protest of Thomas Wakley against the undemocratic powers of the Council of the College in his day. The President declared that the resolution had been carried unanimously, and the meeting closed after a brief discussion as to the membership of the Society of Members, during which Dr. Roche volunteered to furnish the numbers on the spot.

ROYAL DENTAL HOSPITAL DINNER AND "AT HOME."—This hospital held its annual "At home" on Nov. 22nd, which was attended by a large number of past students as well as visitors from other hospitals. Many clinical cases of dental interest had been collected. Among them were rare conditions, such as leontiasis ossea, osteitis fibrosa, macroglossia, odontomes of various kinds, and angioma of the palate. Orthodontics was represented by children showing almost every variety of irregularity of the teeth. Completed cases were presented, which afforded a striking contrast to the original condition as shown in the models and exemplified the successful character of the treatment. The prosthetic side of dentistry was represented by a number of patients wearing dentures made by pupils. The work showed a high standard of excellence which was the more striking since the cases were all of unusual difficulty. Patients who had been trained in the speech clinic attached to the hospital were also present. Pathological, microscopical, and radiological exhibits were also shown. The dinner was held at the Trocadero in the evening of the same day and was presided over by Mr. Warwick James, a former member of the staff. Mr. James, in proposing the toast of "The Hospital," sketched its career from its foundation in Soho-square in 1858, to its present site in Leicester-square. He said that two dentists who had received their education in the hospital in Soho-square were still alive, Sir Charles Tomes and Mr. Howard Mummery. The hospital had produced many eminent dentists and there was scarcely a dental hospital in England which had not a "Royal" man on its staff. Mr. Stobie, the Dean, in his reply, said that the hospital now had 202 students. A new children's department had been equipped, and a legacy by the late Frederick Lonnon had been used to found a bursary which would be awarded on the subject of the treatment of dental disease in children. A new radiological department had been made and a large sports ground acquired which was already in use. He foreshadowed a more extensive development of post-graduate teaching. Mr. Coysh responded for the past students, and Mr. Cohn, the Saunders Scholar, for the present students. "The Health of the Visitors" was proposed by Mr. N. Grellier and responded to by Sir John Bland-Sutton, who said that when he commenced teaching anatomy at the Middlesex Hospital there were a good many dental students. He soon found that the descriptions of the teeth in the text-books on anatomy was belated and he obtained permission to attend the lectures at the Royal Dental Hospital, then in Soho-square. The lecturer in that subject was Sir Charles Tomes and from that time dated his interest in odontology. At first the hospital was started to alleviate pain of dental origin; but it was seen realised by some of those connected with the hospital that dental surgery must come to be regarded as a branch of general surgery, since it was based on anatomy, physiology, and pathology. A feeling began to grow up which had increased since the war, that the dental surgeon should not only look after the teeth, but should take over the treatment of infections and injuries of the jaws, just as the orthopædic surgeon had taken over the treatment of diseases of bone. He thought that the time was coming when general hospitals, especially those engaged in teaching, would have to provide beds for the treatment of dental disease, and that the dental surgeon would be on the same footing as the ophthalmic surgeon, orthopædic surgeon, and laryngologist. It was said that the most indestructible part of the body was the bones and teeth: recently, at Charing Cross the bones of a mammoth had been found, and he himself had found the teeth of the mammoth in a tunnel being bored under the Thames. Yet in the living man the teeth and bones were easily destroyed by infective processes. It was found in the war that a bone could be reduced to the consistency of cheese as a result of infection following gunshot wounds. There was still much to be learned about the development of bone, and they did not know the forces which caused the eruption and loss of the teeth. He was glad to see the position held by odontology at the present time and that it continued to attract so many gifted minds.

MEDICO-LEGAL SOCIETY.—The annual dinner will be held at the Holborn Restaurant, London, W.C., on Friday, Dec. 12th, at 7 for 7.15 P.M., when Lord Justice Atkin, the President of the society, will preside. The price of the dinner is 14*s.* 6*d.*, exclusive of wines.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS.—A meeting will be held on Dec. 10th, at 8 P.M., at Essex Hall, Essex-street, Strand, when Miss Eleanor F. Rathbone will lecture on Family Endowment and Birth Control. Mrs. Marie Stopes, D.Sc., in the chair.

SCOTTISH WOMEN'S HOSPITALS' ASSOCIATION OF THE ROYAL FREE HOSPITAL.—The annual meeting of this association will be held at the hospital, Gray's Inn-road, W.C., to-day, Saturday, Nov. 29th, at 3 P.M. Lady Ossulston will be in the chair.

WE are informed by Messrs. Allen and Hanburys, Ltd., and The British Drug Houses, Ltd., that Dr. S. W. F. Underhill, now senior demonstrator of physiology at St. Bartholomew's Hospital, has accepted an appointment as research physiologist in connexion with the production of "A.B." Brand Insulin.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The Finlayson memorial lectures were delivered by Sir Leonard Rogers, F.R.S., in the Faculty Hall, Glasgow, on Nov. 20th and 24th. The subject of the lectures was "Pathological Evidence Bearing on Disease Incidence in Calcutta," the first lecture being "Disease in General" and the second "Tumours, Simple and Malignant."

THE LATE SIR MALCOLM MORRIS.—The consulting and active staff of St. John's Hospital, Leicester-square, together with the staff of lecturers at the London School of Dermatology attached, have subscribed for a lecture-desk, with a suitable inscription-plate, which has been placed in the theatre in memory of their friend and colleague, Sir Malcolm Morris, who was a member of the consulting staff at the time of his death in February last.

ELIZABETH GARRETT ANDERSON HOSPITAL.—In support of the Extension Appeal Fund for this hospital, Lady Plender, the treasurer, has received a letter from Queen Alexandra, wishing success to the hospital, and continuing: "Queen Alexandra remembers with pleasure that she laid the foundation-stone of the present building, and Her Majesty hopes that all who have at heart the welfare of women and children will help the Extension Appeal Fund, and render service of some kind to forward the success of the enlargement of the hospital of which she is patron."

DONATIONS AND BEQUESTS.—Mr. Tom Hards Wesley, Bournemouth, gave his residuary property, amounting to about £28,000, as to one-third to Dr. Barnardo's Homes, one-fourth to Lord Mayor Treloar's Cripples' Home and College Alton, one-fourth to St. Dunstan's Hostel for Blinded Sailors and Soldiers, one-sixth to the Brompton Hospital for Cancer.—Mr. E. F. Callister, of Birkenhead, has given £2000 to the Liverpool Royal Infirmary for the new equipment in the X ray department, and the same institution has received this year's final contribution of £1600 from the Liverpool Hospital Saturday and Sunday Fund; and from the same Fund the Liverpool Maternity Hospital has received £240 and the Royal Liverpool Children's Infirmary £540.—Miss Dorothea Vanderstegen, of Caversham, Oxon., left £1000 to the Children's Hospital, Paddington Green, London, W., for an "Erle Cot" in memory of Henry Percival Erle and Grace Ellen Erle, and £500 to Dr. Barnardo's Homes.—Miss Emma Rundle, St. Austell, Cornwall, left the residue of her estate, amounting to about £4700, to the National Institution for the Blind.—Miss Ethel Maitland, Ryde, Isle of Wight, left £500 each to Dr. Barnardo's Homes, to the Portsmouth and South Hants Eye and Ear Infirmary, and to the Treloar Home for Crippled Children.—Mr. Archibald Davies, naval architect, of Aigburgh, Liverpool, left £15,400. Subject to a few inconsiderable legacies he left practically the whole of his estate to the Stanley Hospital, Liverpool.—By the will of the late Mrs. M. E. Salting the testatrix left among other bequests £2000 each to the Middlesex Hospital, St. Mary's Hospital, Paddington, and the Cancer Hospital, Fulham-road; £1000 each to the Brompton Hospital for Consumption and King's College Hospital.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Dec. 2nd.

ORTHOPÆDICS: at 8.30 P.M.
Discussion:
On Diagnosis and Treatment of Affections of the Sacro-Iliac Joint, to be opened by Mr. P. Jenner Verrall.

PATHOLOGY: at 8.30 P.M.
Laboratory Meeting at the London Hospital, E.
Prof. W. Bulloch: Disinfection of Catgut.
Dr. G. T. Western: Routine Diagnosis of Gonorrhœa by Cultures.
Dr. P. Fildes: Preparation of Serum for Culture Media.
Prof. H. E. Roaf: Analysis of Colour Blindness.
Dr. W. A. M. Smart: Nomography Applied to Medicine.
Prof. W. Wright: Pathological Specimens.
Mr. F. A. Hocking: Inaccuracy of Syringes.
Prof. H. M. Turnbull and Dr. Dorothy S. Russell: Pathological Specimens.

Wednesday, Dec. 3rd.

SURGERY: at 8.30 P.M.
Discussion:
On the Diagnosis of Malignant Disease of the Thyroid Gland, to be opened by Mr. James Berry.
The following have agreed to speak: Mr. Wilfred Trotter, Mr. A. J. Walton, Mr. T. P. Dunhill, Dr. G. W. Nicholson, Sir Charters Symonds.
There will be a demonstration of specimens and microscopic slides, arranged by Mr. Berry and Dr. Williamson, during the afternoon, from 3 P.M.

LARYNGOLOGY.
Members of this Section are specially invited to attend this meeting.

Thursday, Dec. 4th.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.
Specimen:
Mr. Sidney Forsdike: Vesical Calculus forming on Foreign Body.
Papers:
Mr. Arthur Crook: The Incidence of Glycosuria during Pregnancy.
Prof. A. Louise McIlroy: The Treatment of Shock and the Relative Loss of Heat and Loss of Weight in the New-born.

DERMATOLOGY
LARYNGOLOGY } at 8 P.M.
ODONTOLOGY
Joint Discussion on
Focal Sepsis in Relation to Diseases of the Skin.
Openers:
Mr. J. F. O'Malley (for the Section of Laryngology).
Dr. H. W. Barber (for the Section of Dermatology).
Sir Kenneth Goadby (for the Section of Odontology).

Friday, Dec. 5th.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases and Specimens will be shown by Mr. A. J. Wright, Dr. Dan McKenzie, Sir James Dundas-Grant, Mr. F. J. Cleminson, Sir StClair Thomson, Mr. Howarth, and others.

ANÆSTHETICS.
The December meeting of this Section is postponed to Dec. 12th.

Saturday, Dec. 6th.

OTOLOGY: at 10 A.M. (Cases at 9.15 A.M.)
Cases and Specimens will be shown by Mr. Sydney Scott, Dr. Dan McKenzie, Mr. Cleminson, Mr. Just, and others.

MANCHESTER MEDICAL SOCIETY.
WEDNESDAY, Dec. 3rd.—4.30 P.M. (at the University of Manchester). Dr. E. B. Leech, Dr. D. Dougal, and Mr. H. Platt: Discussion on Chronic Backache in Women.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

Monday, Dec. 1st, to Saturday, Dec. 6th.—West Lecture Hall, Royal Society of Medicine, 1, Wimpole-street, W. Lecture arranged by the Fellowship of Medicine, and open to all members of the profession. At 5.30 p.m., Monday, Dec. 1st, Mr. Herbert J. Paterson: Cancer of the Stomach.—Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynæcology. Lecture-Demonstrations in the Wards and Out-patient Departments. Third week.—Infants Hospital, Vincent-square, Westminster, S.W. Special Course in Diseases of Infants consisting of Clinical Demonstrations, "Round Table" consultations, lectures, &c. First week.—Hospital for Diseases of the Skin, Blackfriars. Course in Dermatology, consisting of instruction in Out-patient Department every afternoon at 2.30, and a Venereal Clinic Tuesday and Friday. First week.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Monday, Dec. 1st.—12 noon, Mr. Simmonds: Applied Anatomy. 2 p.m., Mr. Addison: Surgical Wards. 2 p.m., Mr. Bishop Harman: Eye Dept.

Tuesday.—11 a.m., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 p.m., Mr. Sinclair: Surgical Out-patients.

Wednesday.—12.15 p.m., Dr. Burnford: Medical Pathology. 2 p.m., Dr. Owen: Medical Out-patients. 2.30 p.m., Mr. Donald Armour: Surgical Wards.

Thursday.—11 a.m., Mr. Simson: Gynæcological Wards. 12 noon, Dr. Scott Pinchin: Diseases of the Heart. 4.15 p.m., Lecture, Dr. Pernet: Psoriasis.

Friday.—11 a.m., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 p.m., Mr. Vlasto: Throat, Nose, and Ear Dept.

Saturday.—9.30 a.m., Dr. Burnford: Bacterial Therapy. 10 a.m., Dr. Saunders: Medical Diseases of Children. 10 a.m., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 a.m. to 6 p.m., Saturdays, 10 a.m. to 1 p.m., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Tuesday, Dec. 2nd.—4.30 p.m., Mr. Norman Fleming: Some Points in Medical Ophthalmology.

Friday.—4.30 p.m., Dr. S. Cochrane Shanks: Gastric Ulcer from an X Ray Standpoint.

Daily: In-patient and Out-patient Clinics in General and Special Departments, Operations, &c.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

Tuesday, Dec. 2nd.—5 p.m., Dr. Haldin Davis: Acne Rosacea.

Thursday.—5 p.m., Dr. J. H. Sequeira: Tuberculosis Cutis.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, Dec. 4th.—4 p.m., Dr. A. M. H. Gray: Tuberculous Lesions of the Skin in Children.

ROYAL DENTAL HOSPITAL OF LONDON POST-GRADUATE LECTURES.

Wednesday, Dec. 3rd.—5 p.m., Mr. A. T. Pitts: Post-normal Occlusion.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

Tuesday, Dec. 2nd.—4.15 p.m., Dr. J. Wharton: Ophthalmic Cases.

Friday.—4.15 p.m., Dr. D. E. Core: Early Mental Disease, its Differentiation and Prognosis.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES. (At 3.30 p.m.)

Tuesday, Dec. 2nd.—(At the Jessop Hospital.) Prof. Phillips: Some Obstetric Difficulties.

Friday.—(At the Royal Hospital.) Dr. Wilkinson: The Diagnosis and Treatment of Obstructive Dyspnœa.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

Tuesday, Dec. 2nd.—4 p.m., Dr. Hynd: The Chemical Constitution of the Urine and Blood in Health and Disease.

ROYAL INSTITUTE OF PUBLIC HEALTH, Russell-sq., W.C. (Course of Lectures on the Health of the Commonwealth.)

Wednesday, Dec. 3rd.—4 p.m., Dr. C. K. Millard: The Disposal of the Dead.

CHADWICK PUBLIC LECTURES.

Wednesday, Dec. 3rd.—5.15 p.m. (at the Medical Society's Rooms, 11, Chandos-street, W.). Dr. W. W. Feldman: Post-Child Physiology and Hygiene.

THE PEOPLE'S LEAGUE OF HEALTH. Course of Lectures on the Mind and What We Ought to Know About It.
(At the Medical Society of London, 11, Chandos-street, W.)

Monday, Dec. 1st.—6 p.m., Dr. W. A. Potts: Crime and Delinquency.

Appointments.

Daley, W. A., M.D., B.S. Lond., D.P.H. Camb., has been appointed Medical Officer of Health for Hull.

Davies, W. J., M.R.C.S., L.R.C.P. Lond., Certifying Surgeon under the Factory and Workshop Acts for Aberayron, Cardiganshire.

Findlay, J., M.D. Edin., Medical Referee under the Workmen's Compensation Act for the Districts of the Blackpool and Kirkham County Courts.

Thomson, Sir StClair, M.D. Lond., F.R.C.S. Eng., F.R.C.P. Lond., Emeritus Professor of Laryngology, King's College, and Consulting Surgeon for Diseases of the Throat and Nose, King's College Hospital.

Wilson, Edric F., F.R.C.S. Eng., Assistant Surgeon, Royal Albert Hospital, Devonport.

Queen Charlotte's Maternity Hospital: Cargill, R. E. D. B.M., B.Ch. Oxf., Senior Resident Medical Officer; Saunders, Roy M., M.B., Ch.B. Edin., and Storey, A. G., M.B., B.Ch. Camb., Assistant Resident Medical Officers.

St. Thomas's Hospital: Cooke, A. M., M.B., B.Ch. Oxf., Turney, H. F., M.B., B.Ch. Oxf., Walker, E. G. L., M.R.C.S., L.R.C.P. Lond., McLean, W. W., M.R.C.S., L.R.C.P. Lond., Thwaites, W. G., M.R.C.S., L.R.C.P. Lond. Gervis, W. H., M.R.C.S., L.R.C.P. Lond., Hudson, M. W. P., M.R.C.S., L.R.C.P. Lond., and Starkey, R. S., M.R.C.S., L.R.C.P. Lond., Casualty Officers and Resident Anæsthetists; Hope-Simpson, J. W., M.B., B.Ch. Camb., Yates, H., M.R.C.S., L.R.C.P. Lond., Creed, R. S., M.B., B.Ch. Oxf., and Berridge, W. C. M., M.R.C.S., L.R.C.P. Lond., Resident House Physicians; Briggs, T. F., M.R.C.S., L.R.C.P. Lond., Resident House Physician for Children: Jeffery, A. L. P., M.B., B.S. Lond., Walford, A. S. H., M.B., B.Ch. Camb., Webb-Peploe, M. H., M.B., B.Ch. Camb., and Metcalfe, G. A., M.B., B.Ch. Camb., Resident House Surgeons: Allan, F. G., M.R.C.S., L.R.C.P. Lond., Resident Orthopædic House Surgeon; Rees, E. J., M.R.C.S., L.R.C.P. Lond., Resident House Surgeon for Ear; Davies, D. V., M.R.C.S., L.R.C.P. Lond., Resident House Surgeon for Throat; Weaver-Adams, E. R., M.B., B.Ch. Camb., Senior Obstetric House Physician; Darlington, A. F. D., M.R.C.S., L.R.C.P. Lond., Junior Obstetric House Physician; Jones, H. V. M., M.B., B.S. Lond., Senior Ophthalmic House Surgeon; Heath, W. E., M.R.C.S., L.R.C.P. Lond., Junior Ophthalmic House Surgeon; Neilson, D. F. A., F.R.C.S. Eng., Oliver, J. O., M.R.C.S., L.R.C.P. Lond., Thompson, W. D. R., M.R.C.S., L.R.C.P. Lond., Barron, H. T., M.D. Lond., Doyle, A. F., M.R.C.S., L.R.C.P. Lond., Taylor Rea, R. H., M.R.C.S, L.R.C.P. Lond., Marriner, H. I., F.R.C.S. Edin., Pilot, R., M.R.C.S., L.R.C.P. Lond., Joseph, W. E., M.R.C.S., L.R.C.P. Lond., Lloyd-Williams, P., M.R.C.S., L.R.C.P., Lond., L.D.S., Barrett, J. C., V.C., M.R.C.S., L.R.C.P. Lond., Boggon, R. H., M.R.C.S., L.R.C.P. Lond., Briscoe, A. D., M.R.C.S., L.R.C.P. Lond., Thompson, J. H. G., M.R.C.S., L.R.C.P. Lond., Archer, E. C., M.R.C.S., L.R.C.P. Lond., Dobie, J. M., M.R.C.S., L.R.C.P. Lond., Marks, D. P., M.R.C.S., L.R.C.P. Lond., Wrigley, A. J., M.R.C.S., L.R.C.P. Lond., Copeman, W. S. C., M.R.C.S., L.R.C.P. Lond., Marcano, G. R., M.R.C.S., L.R.C.P. Lond., Shires, B., M.B., Ch.B. Edin., de Jersey, G. W. S., M.R.C.S., L.R.C.P. Vacancies.

For further information refer to the advertisement columns.

Belgrave Hospital for Children, Clapham-road, S.W.—Res. M.O. at rate of £100.

Cambridgeshire Tuberculosis Colony.—H.P. £100.

Charing Cross Hospital, W.C.—Res. M.O. £400.

Chelmsford Administrative County of Essex.—Two Asst. County M.O.H.'s. Each £600.

Croydon General Hospital.—Hon. Orthop. S.

Derbyshire Royal Infirmary.—Hon. Asst. S. Also Ophthal. H.S. £200.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.S. at rate of £125.

Exminster, Devon Mental Hospital.—Jun. A.M.O. £300.

Gordon Hospital, Vauxhall Bridge-road, S.W.—Res. H.S. at rate of £75.

Greenwich, Dreadnought Hospital.—H.P. and H.S. at rate of £150.

Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—H.P., and H.S. Also Cas. Med. O. and Cas. Surg. O. All at rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each £50.

Kingston Union Hospital.—Asst. R.M.O. at rate of £350.

London Hospital, E.—First Asst. to Medical Firm. £400.

London Lock Hospital, 91, Dean-street, W.—Clin. Asstships.

London Lock Hospital, 283, Harrow-road, W.—Second H.S. £150.

London Temperance Hospital, Hampstead-road, N.W.—R.M.O. at rate of £175.

Maidstone, Kent County Mental Hospital.—Asst. M.O. £300.

Manchester Christie Hospital.—Cancer Research Worker. £500.

Manchester, Eccles and Patricroft Hospital.—H.S. £200.

Manchester Hospital for Consumption, &c., Bowdon, Cheshire.—R.M.O. £200.

Manchester Royal Infirmary.—Hon. Asst. Radiologist. Also R.M.O. £200.

Miller General Hospital, Greenwich-road, S.E.—Part-time Asst. to Out-patient Dept. £150.

Ministry of Health, Whitehall, S.W.—M.O. £600 and bonus.

Oxford, Radcliffe Infirmary and County Hospital.—H.S. and Obstet. H.P. Each at rate of £120.

Oxford, The Warneford.—Second Asst. M.O. £250.

Park Royal Hospital, Acton Lane, W.—Res. Asst. M.O. £350. bonus, &c.

Poplar Hospital for Accidents, East India Dock-road, E.—Hon. Dent. S.

Prince of Wales's General Hospital, N.—Hon. Clin. Assts.

Queen Mary's Hospital, Stratford, E.—Res. M.O., H.P., two H.S.'s, Obstet. H.S., and H.P. and Cas. O.

Rotherham Hospital.—Hon. Radiologist.

Royal Army Medical Corps.—Commissions.

Royal Free Hospital, Gray's Inn-road, W.C.—Surg. and Gynæcological Reg. £250.

St. Giles' Hospital, Camberwell, S.E.—Consultant Dental Surgeon.

St. John's Hospital for Diseases of the Skin, Leicester-square, W.C.—Hon. Asst. P.

St. Peter's Hospital for Stone, &c., Covent Garden, W.C.—Clin. Assts.

Sheffield Royal Infirmary.—H.S., Asst. Cas. O. and Asst. Ophth. H.S. Each £60.

Sheffield University.—Asst. Pathologist. £500.

Staffordshire General Infirmary, Stafford.—H.S. at rate of £150.

West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Asst. P., Laryngologist. Also Otologist.

West London Hospital, Hammersmith-road, W.—H.P., H.S., Aural H.S. and Res. Cas. O. Each at rate of £100.

Wigan Infirmary.—Third H.S. at rate of £150.

Willesden General Hospital, Harlesden-road, N.W.—Vacancy on Hon. Med. Staff.

Winchester, Hampshire County Council.— Asst. M.O.H. £600.

Windsor, King Edward VII. Hospital.—Jun. H.S. at rate of £100.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Coalville, Leicester; Kirriemuir, Forfar.

Births, Marriages, and Deaths.

BIRTHS.

COURTNEY.—On Nov. 17th, the wife of J. M. Courtney, M.R.C.S., L.R.C.P., of Castle Hill House, Lynton, North Devon, of a son.

MULLINS.—On Nov. 18th, at New-street, Wells, Somerset, the wife of Dr. G. E. Mullins, of a daughter.

SHIPTON.—On Nov. 18th, at Buxton, the wife of William Shipton, M.D., of a daughter.

MARRIAGES.

MOORE—O'CONNOR.—On Nov. 13th, at St. James's Church, Spanish-place, William A. Moore, M.B., B.A., Freshford, Co. Kilkenny, Ireland, to Mary O'Connor, M.B., B.D.S., Woburn-place, London.

DEATHS.

COUMBE.—On Nov. 10th, at Tunbridge Wells, John Batten Coumbe, F.R.C.S., aged 71.

DIXON.—On Nov. 17th, at Newlands, Sheringham, Thomas Arthur Dixon, M.D., Lieut.-Colonel, late R.A.M.C., aged 71.

GLENISTER.—On Nov. 17th, at Fairlight, Sussex, Wilfrid Montague Glenister, M.R.C.S., L.R.C.P., of "The Lindalls," Amberley.

LINDSEY.—At Sunny Bank British Hospital, Cannes, S. France, on the 19th inst., Mark Basil Lindsey, late of "Beaumont," Portman Crescent, Bournemouth, M.R.C.S., L.R.C.P., Capt. R.A.M.C., 1915–19.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

VISION IN THE AIR SERVICES.

BY KENNETH R. SMITH, M.D., B.S. LOND.,

LATE R.A.F. MEDICAL SERVICE.

BINOCULAR vision is necessary for flying, and this necessity has compelled the Air Services in this and other countries to pay great attention to the subject. The pilot has to estimate his distance from the ground when he wants to land, and has no help from perspective, for the gap between his moving plane and the earth or sea beneath it has no series of objects leading from one to the other as along a road, and his estimate depends entirely on the sense of space obtained by vision with both eyes together. If this fails him, he is liable to "flatten out" too soon or too late; the former makes his plane drop to the ground instead of gliding on to it, and the latter may drive the nose of the plane forcibly to earth with disastrous results.

Necessity of Binocular Vision.

Bad landings from errors of visual judgment appear to be the universal experience in all countries where there is flying. The United States Air Service Medical Manua mentions defect of visual judgment as one of the greatest causes of exclusion from the Service, and that this is due t a failure in binocular vision is certain. Anyone intereste should be thoroughly convinced of his inability to estimat distance with one eye, and for this purpose a small apparatus made of wire and resembling a street lamp in shape, is kep at the Central Medical Board R.A.F., so that every medica officer may try for himself and know from his own observation that he cannot estimate distance with one eye alone. A piece of wire bent into two rings thus, O O, serves equall well; it should be held up to the light and looked at wit one eye while the other is firmly closed. If the small en is further away from the eye it may appear to come nearer as if the little apparatus was turned inside out; but, in an case, there is no visual certainty of the relative position of th two rings until the other eye is opened, when it is impossibl to deceive oneself as to their relative position, and it becom easy to understand the confidence which normal binocula vision gives to a pilot when he is landing, and the uncertaint in the process when he has the vision of only one eye t guide him.

There is nothing newly discovered in this; that man people have a "master eye" is a familiar fact, and if th master eye happens to be the left one it has been foun inconvenient for shooting, and to this extent it has bee regarded as a disability. The needs of flying have demonstrated that the disability, which a habit of using the visio of one eye only involves, is of far greater importance—tha it destroys the visual judgment which is essential to th man who flies and is needed in the ordinary affairs of dail life, especially to the man who drives a car or who strive for excellence in ball games, but also to the factory han and whenever there is visual control in action. A liabilit to loss of visual judgment from monocular vision may serv as a definition of this defect.

Examination of the Eyes.

The following is an account of the routine eye examinatio in the R.A.F.:—

The vision of each eye is tested in the usual way wit test types at six metres, and the examination for errors o refraction is carried out. Myopia is considered an objection but the acceptance of a plus lens of low power is favourabl regarded. Colour vision is also investigated.

Four tests are mainly relied on in reference to the questio of normal binocular vision:—

(1) *Test for Power of Convergence.*

Hold a pencil in front of the patient about 12 inche from his eyes, with the point on a level with the root of th nose. Tell him to look at the point, and then move i steadily towards him and observe what happens to hi eyes as it approaches them.

(*a*) Both eyes may converge, "fixing" the point of th pencil until it is within an inch or two from the root of th nose. This shows that the power of convergence is ver good, and the result is recorded as V.G. under the headin *convergence*, and a note is made of the distance of the poin of the pencil from the eyes at the termination of the test.

(*b*) As the pencil point approaches one eye may cease t turn inwards to "fix" it, and may even wander outwards The distance of the point of the pencil from the eyes whe this occurs is noted under the same heading, thus: V.G inside 2 in.; G., from 2 to 3 in.; Fair, from 3 to 4 in. Poor, outside 4 in.

(*c*) Both eyes may fail to keep up fixation. The patient may even resist by throwing back his head, or/and complain either that "it hurts him to follow the pencil" or that he "sees double" when the pencil is nearer his eyes than 10 inches. *In such cases convergence is defective.*

(2) *Cover Test.*

Hold a pencil in front of the patient and ask him to look at the point of it as before. Cover one eye for a few seconds, and then uncover and observe whether the eye moves as it is uncovered.

(*a*) There may be no movement; both eyes may remain "fixed" on the point of the pencil whether one eye is covered or not. This is the normal condition.

(*b*) There may be movement inwards or outwards on uncovering. The eye which has been covered has not remained "fixed" on the point of the pencil and moves to regain its position when the cover is taken away. This failure to remain "fixed" is described as latent divergence or latent convergence, and the recovery from it may be rapid, sluggish, or slow, and it may be preceded by an observable pause or lag. Movement indicates defect of ocular muscle balance, rapid recovery shows that it is slight, delay indicates greater defect.

(*c*) Both eyes may move on uncovering. The one which was covered "fixes" the point of the pencil, and the other moves away and then regains its position. This has been called "refixation," and indicates that the eye which was covered was a "master eye."

(3) *The Bishop Harman Diaphragm Test.*

With the instrument set for the measured distance between the pupils, and the letters A B C D E F G on the card, it will be found, approximately, (1) that with the aperture fully open all the letters except the two outside ones are seen by both eyes; that as the aperture is lessened, (2) at 15 the letters A B C D E are seen by the right eye and C D E F G by the left eye, so that the three letters C D E are seen by both eyes; (3) at 5 this number is reduced to one, the D only is seen by both eyes—that is, the right eye sees A B C D and the left eye sees D E F G; (4) at zero half of the D is seen with one eye and half of it with the other, *no part of the set is seen with both eyes.*

The patient takes the instrument and is told to look through the aperture at the letters, to direct his gaze to the central one, and to report at once if anything happens. The aperture is then steadily lessened. The index may arrive at zero without anything happening—that is, the subject still sees all the letters in their true position as at first; this is evidence of good ocular muscle balance, for he is seeing half of the set of letters with his right eye and the other half with the left eye, and the eyes are maintaining their position as truly as when the set was seen by both eyes.

Or the patient may report that something is happening before the index arrives at zero—for example, when it points to 5 he may say (*a*) that he only sees A B C D; this is evidence of "neglect" in the left eye, for he sees only the letters then visible to the right eye. (*b*) Or he may say that the letters have divided into two sets, A B C D on one side and D E F G on the other, with a dark line between them; this is evidence that one eye has turned outwards (exophoria), and as D is seen in each set of letters, of diplopia. (*c*) Or he may say that the middle letters crowd together and overlap one another, indicating that the eyes have turned inwards (esophoria). (*d*) Or that the letters on one side have taken a higher or a lower level than those on the other side (hyperphoria or hypophoria).

The aperture can be lessened below the zero mark on the scale, so that the middle letter is not seen by either eye, and the edge of the shutter may be seen as a black line in its place; if, when this occurs, the other letters maintain their position as at first, a perfect condition of muscle balance is indicated.

On the other hand, if at any point the appearance of the letters is altered as specified in the paragraphs (*a*), (*b*), (*c*), and (*d*), this indicates that at this point binocular single vision is just breaking down. If this occurs at any point over 3 on the scale defect is indicated.

Subsequent tests after a period of eye-training serve to show whether improvement has taken place, and, if so, to what extent.

The Bishop Harman diaphragm test thus serves to show: (1) perfect binocular single vision, (2) its liability to break down, (3) the direction in which the eyes move when the breakdown occurs, (4) the neglect or double vision which attends this movement.

(4) *The Red-Green Test.*

This test is based on the fact that red glass of suitable density will not allow green light to pass through it, and vice versa, so that spectacles in which red glass covers the right eye, and green glass covers the left one, deprive the right eye of the power of seeing green and the left eye of seeing red. Such spectacles are used in this test, and the patient wearing them is requested to look at an illuminated slot in a box 20 feet away from him. This slot, 5 in. by $\frac{1}{2}$ in., is vertical and is glazed for half its length with red glass and for the other half with green glass. A similar slot placed horizontally can be used if desired. The patient equipped with the spectacles sees the red half of the slot with one eye and the green half with the other.

He is asked to describe what he sees and may say:—

1. That he sees two lights, the red and the green, (*a*) in their proper position one above the other—this indicates correct ocular muscle balance. (*b*) That one light is to the right or to the left of the other or that it is displaced upwards or downwards. This indicates loss of ocular muscle balance, exophoria or esophoria, and/or hyperphoria or hypophoria. (*c*) That one of the lights wanders from its original position and back again; this shows a tendency to heterophoria, with some or full power of correction.

2. That he sees two lights at first but that one disappears occasionally; this indicates the presence of a master-eye if it is always the same light which disappears, or of alternating neglect if there are occasional disappearances of one or the other, the red or the green.

3. That he sees "either colour singly, but never the two together."

N.B.—The two colours must be completely separated to constitute evidence of the existence of heterophoria; when they touch one another corner to corner it is noted as a tendency to it only.

Interpretation of Results of Tests.

These four tests are directed mainly to discovering whether there is any lack of perfect coördination in the movements of the eyes. There may be direct evidence of neglect in the Bishop Harman diaphragm test by the disappearance of one-half of the letters, or by the disappearance of the red or the green in red-green test; but what one is trying to discover is (1) whether the subject of the examination always uses both eyes together or (2) whether he sometimes uses both together and at other times uses only one; he may have a habit of using the right eye and neglecting the vision of the left, he then has a master-eye (the right one in this case, but it may be vice versa); or he may have a habit of "alternating neglect," that is, his vision is sometimes binocular and sometimes "one-eyed," but the neglect may be in either eye. The cover test shows just what the neglected eye does when it ceases to have its share of attention, it tends to turn away from the direct line of vision. If, then, the tests show that the condition of ocular muscle balance is normal, that when, without the knowledge of the subject, each eye is acting independently of the other, they keep their direction truly, and show no tendency to wander from it, in or out, up or down, it is a practical certainty that they have no habit of doing so, and that binocular vision is not liable to disturbance but is constant.

On the other hand, with any marked degree of loss of ocular muscle balance, the fact that with one eye directed to an object the other readily turns away from the line of direction, is evidence of its liability to do so, and possibly of a habit of doing so, and double vision would result from it unless there were "neglect." There is no history of double vision, so that loss of ocular muscle balance in these cases with good vision in each eye indicates a liability to monocular vision and the loss of visual judgment essential to the pilot, together with the confidence which attends binocular vision.

HEALTH PROBLEMS IN THE CAMEROONS.

A REPORT for the year 1923 on the Cameroons Province, as administered by the Government of Nigeria under mandate, has been issued recently. For administrative purposes the territory is divided into four divisions—Bamenda, Mamfe, Buea with Kumba, and Victoria. Medical officers are stationed when available at these centres, with a native dispenser attached to each station. It may be said that each of these areas has its localised diseases and sanitary problems. These are but slightly affected by the ex-German hospital and sanitary arrangements, as the areas which have to be served by the stations are very extensive and the bulk of the people not advanced in questions of public health. The natural advantages of the country, it being for the most part of a mountainous nature with a relatively low temperature and good natural drainage and water-supply, counteract many of the evils which would otherwise flourish. In the forest area the soil is mainly clay and natural drainage poor. There is no attempt among the natives to instal any system of soil-disposal other than shallow pits scratched in the jungle close to the village, and with no regard to the source of drinking water, which is generally the nearest stream. It is understood that the "street-system" of villages throughout this area was the invention of the Germans for political reasons. A description of a typical village may be of service: A wide road, beaten flat by constant traffic, along which the town extends on either side, with as few breaks as possible to avoid separate walls and roofs in construction of the houses; the length of this street is limited only by the number of inhabitants, and forms a tunnel along which ventilation is only possible in the line of the street; the houses, low and dark, built flimsily of wattle and daub, with poorly-thatched roofs, lighted and ventilated, as a rule, only by a low door at front and back; no shade along the road, which may run for three miles through a village of this type; no trenching in front of or behind the houses and clearing of bush behind, so that all refuse and night soil is deposited a few yards from the dwelling. Cultivation is, as a rule, some distance from the village, so that the latter does not obtain the benefit of cleared and clean ground around it. Throughout the area a common source of income appears to be pig-breeding, these animals being neither fed nor penned, and drawing their food from jungle weeds and village garbage, with free access to either. The staple food of the people is the bulb of the "coco-yam" arum lily, which is a bulky and perishable article of small nutritive value. It is, however, fairly easy of cultivation. Around the food question revolves the vital and vicious circle of infant mortality. This depends on the well-being of the expectant mother, whose status appears to be low in the Cameroons, where all the manual labour of the farm and the house falls to her share. The people themselves are most anxious to seek treatment for their children, who come to the local dispensary in large numbers for medicine. On the other hand, the great majority of the people appear to be chronically underfed, and women overworked while young and neglected when old; the staple diet is inadequate for young children and the sick, who fall an easy prey to such complaints as ulcer, skin diseases, and intestinal parasites.

In Bamenda the country enjoys great assets in being well drained, with a temperate climate, and in possessing good food supplies. Large quantities of potatoes, introduced by the Germans, are grown by the natives for their own consumption. The hilly nature of the division has prevented the collection of villages along the main roads, and the settlements are farms where best suited for tillage. The water-supply is abundant and fairly free from contamination, being from mountain streams; and the general type of native sturdy and remarkably free from the chronic ailments that are seen in the forest area drained by the Cross River. The system of plantations around Victoria has hitherto employed large numbers of natives. These men and boys receive free medical treatment in hospitals, of which there is one on every plantation, with native dressers and attendants under the supervision of the medical officer. There have been no widespread epidemics and a remarkable absence of diseases attributable to the nature of the work. Serious cases can be transferred to hospitals at Buea or Victoria directly under the supervision of the medical officer.

Throughout the Cameroons the people have willingly submitted to vaccination and to medical instructions regarding isolation and treatment of infectious cases. A large number of cases of acute broncho-pneumonia occur at "the change of season," from the dry to the wet and vice versâ; the natives themselves attribute this to the effects of the influenza epidemic of 1918. It is probable that the effect of that epidemic will linger for some time, especially in the areas of overcrowding and heaviest rainfall. It is hoped to establish small dressing-stations of the nature of "aid-posts" under the direction of the medical officers and staffed by natives sufficiently trained to use simple remedies, who will advise the local inhabitants in sanitary measures. With improved communications it will assuredly be found that not only will the people be able to seek medical advice more freely, but that the freer exchange of commodities will raise the standârd of living and increase the food-supply, with improvement of the health of children. The fact that the birth-rate is low does not appear to be due to venereal disease, few cases of which are seen except in the stations, where they appear to be imported and do not go with a system of general prostitution. Promiscuous relations seem generally due to the inability of the man to pay the dower asked for a girl, who may thereupon decide to live with her "friend" for a period, depending on his whims or means. As such union gives her no claim on the children, the discarded woman has to find another refuge, having no independent means. The practice of holding the children of marriage in bond to the woman's parent until the whole dower is paid has also an adverse effect on the increase of families; and as the man in a position to afford several wives is usually elderly, there are few children in proportion born to him, with the added disadvantage that the offspring of the young and healthy women of a village may be nearly related by blood.

Report of the Director of Medical and Sanitary Services.

The Director's report gives such information as is available in regard to the incidence of certain tropical diseases. No case of sleeping sickness has yet been reported or come under observation in any of the areas where a medical officer is stationed, but tsetse-flies are known to be present, and it is probable that sleeping sickness occurs. Buea and Kumba report 25 cases of tuberculosis, with three deaths, and five cases are recorded in Mamfe. Victoria and Bamenda record no cases. There is no evidence as to what the death-rate may be and no statistics by which increase or decrease can be indicated. It is probably much more prevalent than is shown by the cases recorded. There were 36 cases of ankylostomiasis treated at Victoria, with ten deaths. Buea and Kumba record 37 admissions and two deaths and 48 out-patients, mainly plantation labourers. Mamfe records four cases; Bamenda none. At Victoria ol. chenopodium was employed in the treatment; in Buea, Kumba, and Mamfe thymol was given. Malaria appears more prevalent in Mamfe district and comparatively rare in Bamenda. It is common in Buea and Victoria. Enlarged spleens are commonly met with in children. Various salts of quinine have been used in treatment, mostly administered by the mouth, but sometimes by intra-muscular injection. Total cases, 1271 Africans, 12 Europeans. There was no case of plague. Filaria loa is reported to be very common in the region of the Mungo River in Victoria district, and also in the Mamfe district. The carrier *Chrysops silacea* is present in large numbers. Filaria bancrofti is reported from Mamfe. Total cases, filaria loa 98, filaria bancrofti 26. Leprosy does not appear to be very prevalent. Twenty cases came under observation and treatment in Mamfe, six in Victoria, six in Buea and Kumba, and three in Bamenda. Treatment was exclusively by moogrol, and improvement was noted. Total cases, 35; no deaths recorded. There was an epidemic of small-pox during the first six months of the year. Only a few of the cases occurred in Victoria, and by far the greater number were in Bamenda. Vaccination was freely carried out wherever possible. Total cases, 499; deaths, 102; vaccinations, 13,730, of which 7859 were successful. Syphilis is very prevalent in the southern part of the territory, in the plantations, and on the seaboard. Treatment was by novarsenobillon and by mercury and the iodides. Total cases, primary 91, secondary 93; congenital syphilis reported as fairly common. In Bamenda the medical officer comments on the incidence of recorded cases, being mainly females, occurring as rapid and extensive destruction of the palate without any previous signs of disease, and on an isolated case in which the patient had a healthy child of 10 months. The infection has probably been introduced by the trade routes and by three classes—viz., traders, labourers, and, in the northern part, African troops. Gonorrhœa is very prevalent in Victoria, Buea, and Mamfe, and to a less extent is found in Bamenda. No figures are given as to the number of cases treated. The sources of the spread of this disease are very similar to those of syphilis. As contributory causes of the spread of venereal diseases may be mentioned: (*a*) the high price of wives; (*b*) the transfer of wives from one purchaser to another owing to failure in paying the instalments of the purchase price; (*c*) desertion of wives brought into the country by traders and others; (*d*) unattached women traders; and (*e*) wandering prostitutes. It is hoped, when details come to hand of the Kenya treatment, to organise a campaign against syphilis and yaws. Registration of births and deaths is not compulsory, and no attempt is therefore made to get these statistics. The only registration that is carried out is that of non-native births and deaths. The following table shows the distribution of the population in the different divisions: Bamenda, 187,862; Victoria, 32,627; Mamfe, 61,078; Kumba, 66,155; total, 347,722.

COLMAN'S BATH MUSTARD.

WE are asked by Messrs. J. and J. Colman, of London and Norwich, to state that the bath mustard noticed in our issue of Nov. 1st, p. 944, is the product of their firm incorporating that of Messrs. Keen, Robinson and Co.

Erratum.—On p. 1086 of our last week's issue the death of Dr. Gersuny, of Vienna, was, by a typographic error stated as the death of Dr. Gersung.

F. W. W.—The annotation in THE LANCET of Sept. 23rd 1922, on Thermometric Scales in which it was mentioned that Gabriel Daniel Fahrenheit was elected a Fellow of the Royal Society is correct. It is true that in the Record of the Royal Society printed for circulation, it is stated that "in 1724 Gabriel Jean Fahrenheit was elected," but this appears to be a mistake. There is only one Fahrenheit in the list and his is the well-known name in connexion with the thermometer.

An Address

ON

SLEEP, SLEEPLESSNESS, AND SLEEPINESS.

Delivered before the Wimbledon and District Medical Society on Nov. 14th, 1924,

BY SIR FREDERICK MOTT, K.B.E., F.R.S.,
M.D. LOND., LL.D. EDIN.

SLEEP is the result of a series of events ending in a loss of consciousness and of voluntary movement. Normally, it begins with a voluntary action: we will to sleep and therefore go to bed—that we do every evening as a habit. But wherein does the act of going to sleep consist? We may wish to sleep and the wish may or may not be fulfilled. To say that by auto-suggestion we fall asleep means nothing.

Since sleep occupies a large part of our life it must be a physiological condition and one of great importance. In fact, it requires no great consideration to make it obvious that without the repetition of sleep healthy mental and bodily life is impossible. When we have been awake for a long time, that is we have exercised conscious mental processes, a condition comes on of weariness causing a desire for sleep, which becomes more and more urgent the longer the waking condition exists. We can voluntarily fight against the urgent desire for sleep to a certain degree and we can prevent ourselves falling asleep by use of artificial means—e.g., such stimulants as strong tea or coffee—but it will be at the expense of health. It is known that a person can live a few minutes without air, a few days without water, and a few weeks without food, but, although he can live several weeks without food, he cannot live a week without sleep. How do we know this? In China, where refined modes of death by torture have been long practised, death by prevention of sleep is one of the methods employed. The victims do not live more than five to seven days. But what is sleep? How does it come to pass? What processes take place in the body? We can subjectively characterise sleep by its most outstanding sign as a loss of consciousness and of voluntary movement. But that is only a superficial explanation of a negative nature which occurs to everyone. Sleep has been defined as: "A state of general marked quiescence of voluntary conscious (as well as of many involuntary unconscious) functions, alternating more or less regularly with periods of activity. In human sleep, when it is deep, the body lies quiet with the muscles relaxed, the pulse-rate lower than during the waking hours, and the respiration less frequent, but deep, while the person does not react to slight sensory stimuli. Intestinal peristalsis is diminished, secretion is less actively carried on; the pupils are contracted, and the brain is said to be anæmic. If the depth of sleep is measured by the noise necessary to waken the sleeper, it reaches its maximum within the first hour, and then diminishes at first rapidly then more slowly." Various theories have been put forward regarding the cause of sleep, but before giving a short account of these theories it will be desirable to turn our attention to the most obvious sign, the loss of consciousness.

SLEEP IN RELATION TO THE STREAM OF CONSCIOUSNESS.

In sleep there is a cessation or partial cessation in the flow of the stream of consciousness. Now what do I mean by the stream of consciousness? Flowing into it continuously by all the sensory avenues are stimuli producing a sensory-motor continuum. For every sensation tends to activation by muscular contraction, and reviviscence of past sensations by association percepts or images. We may group sensations into two great classes: External and Internal.

1. The *External* or *Exteroceptor* are (1) the distance receptors: sight, hearing, and smell; (2) contact receptors: taste, touch, pain, heat, and cold; (3) gravitation. These form together a subjective feeling continuum which may be termed exæsthesia.

2. *Interoceptor.*—Seeing that every sensation and every mental image or engram leads to a reflex activation which may be apparent or not according to the influence of positive or negative inhibition; to every sensation and image or perception there must, in consequence of this reflex motor action, result a corresponding kinæsthetic or postural excitation of afferent stimuli flowing along proprioceptive neuronic systems from muscle spindles, tendons, bones, and joints which, combined with associated labyrinthine sensations, form a sensory continuum which is intimately integrated with the exteroceptor sensory continuum on the one hand and the motor continuum on the other. This proprioceptive-labyrinthine continuum forms the less conscious but quite as important framework—the warp upon which the exteroceptor continuum, the woof, is woven. The two are inseparable, and the kinæsthetic and postural alterations in this sensory continuum, although playing apparently a subordinate part in the field of consciousness, really are most important in reviviscence of memory images or engrams. But under interoceptor stimuli we have to consider also those which form a continuum that minister to the vegetative functions or organic needs of the body. These are characterised by low intensity in normal conditions, and it is only when these stimuli rise above or below the normal intensity, or vary in their normal phasic rhythm or periodicity, that we become aware of their existence by their entry into the stream of consciousness. This state of feeling is termed cœnæsthesia.

The interoceptor and exteroceptor stimuli are integrated and constitute the subjective personality or ego. The sensation complexes or, if you like, excitation complexes, to use a synonym, form a continuous conscious and subconscious series which tends to reviviscence of a series of past experiences either in the form of concrete images or engrams or of abstract symbolic verbal images or engrams. The stream of consciousness is largely made up, in civilised people, of a continuous flow of engrams or images of verbal symbols forming concepts (silent language). Every fresh excitation exteroceptor or interoceptor arouses usually the equivalent word symbol. Abstract thought depending as it does upon language is only acquired by imitation. For, hearing no language we should speak no language, and in the uneducated deaf-mute, and to a less degree the primitive savage, the stream of consciousness is largely made up of a succession of sensation complexes and revived images or engrams of concrete objects and their associations in time and place.

The more highly cultured a man, the more does his mental furniture depend upon word symbols. It is an interesting question whether these word symbols constituting silent thought can be revived in the complete absence of exteroceptor stimuli. When we lie awake at night and external stimuli of sound and light are greatly diminished, so that the principal external tributaries to the stream of consciousness are almost dry, there often arises a flow of ideas; apparently the stream of consciousness is swollen and overfull with the flood of ideas. The lamp of attention is compelled to chase this succession of ideas made up of reminiscences of past experiences, or of creative imagination, which usually is of the nature of fantasy, more rarely of useful invention. This flow of ideas is a condition between sleeping and waking and is termed the hypnagogic state. There is partial consciousness; the inability to check this flow of ideas is due to failure of the highest inhibitory level of the cortex, owing to acquired or innate conditions leading to exhaustion as in neurasthenia, or the effects of a toxin as exemplified by the delirium of fever.

As a result of failure of function of this evolutionally and developmentally highest level there is a facilitation of associational ideation. This weakening or failure of inhibition prevents volition and choice of thought. It might be asked, would this stream of consciousness, which we may term endoæsthesia as distinctive from exoæsthesia and cœnæsthesia, flow in the complete absence of exteroceptor stimuli? Physiologists quote a case of Strumpell's of a woman who had lesions in the mid-brain and base of the brain, which deprived her of all sensibility except the sight of the left eye and hearing of the right ear. If the ear was plugged with wax and the eye closed the patient became unconscious and fell asleep.

We know also that consciousness depends upon a constant supply of arterial blood, for Mosso the physiologist made this experiment upon a man who in consequence of an injury to the skull had the brain exposed so that pulsation could be felt in it. When he compressed the carotid arteries the pulsation stopped, the man was told to count, and invariably when six seconds had elapsed the man lost consciousness. It was restored upon return of pulsation. There was dissociation of the ganglion cells of the cortex at their synapses—at least that seems the most probable explanation. This dissociation may be due to an alteration of surface tension at the multiple points of contact in consequence of deprivation of oxygen. Seeing that the lower subcortical centres can continue functioning a much longer time than six seconds when deprived of blood, it follows that the ganglion cells in the highest level of the cortex are more easily exhausted.

Physiological Experiments.

Many physiological experiments have been performed with the object of seeing the changes which take place in the brain during sleep. Arthur Durham trephined animals and placed a watch-glass in the aperture, and he found the blood in the vessels is diminished in amount and does not move so rapidly. He also noted that whatever increases the cerebral circulation tends to wakefulness. Dr. William Hammond and Dr. Silas Weir Mitchell repeated Durham's experiments and obtained the same results.

Dr. Angelo Mosso made observations upon three patients who had lost a portion of the cranial vault, and in whom there was a soft pulsating cicatrix. He found that during sleep there is a less amount of blood circulating in the brain, and at the same time an increased amount in the extremities. He showed further by the aid of the plethysmograph that there are frequent adjustments in the circulation during sleep. Thus a strong stimulus to the skin but not enough to waken the sleeper caused a contraction of the blood-vessels of the forearm, a general rise of blood pressure, and a determination of blood towards the brain; and, on the other hand, upon suddenly awakening the sleeper, there was a contraction of the vessels of the brain and an accelerated flow of blood through the hemispheres. The whole organism is so sensitive during sleep that a loud sound, light, a touch, or any moderate sensory impression modified the respiratory rhythm, determined a contraction of the vessels of the forearm, increased the blood pressure, caused an increased flow to the brain, and quickened the beats of the heart.

These experiments are in agreement with the observations of other physiologists, Donder, Kussmaul, Turner, and others. It is, therefore, probable that during sleep there is a partial anæmia of the brain, and that the blood is determined away to other organs and tissues, whilst at the same time this partial deprivation of blood may be modified by changes in the circulatory or respiratory mechanism caused by sensory impressions, or by sudden changes in position, or the state of response of the muscles. Examination of the retina during sleep shows a partial anæmia as compared with the waking state. Several other theories of sleep besides cortical anæmia have been put forward, one was that the pituitary gland pours out a secretion into the brain that causes sleep; another that it is a vegetative function of the body the highest controlling centre of which is in the hypothalamic region. This view will be considered later when dealing with lethargic encephalitis. Then there is the theory of Mathias Duval that sleep is due to dissociation of the cortical ganglion cells by retraction of the terminal gemmules of the dendrites or of the terminals of the axons by a process allied to amœboid movement.

But these physiological investigations, however, have never furnished a quite satisfactory explanation of the series of events which lead up to sleep, and there is much to be said in favour of a biological explanation. Throughout organic nature there has been an association between functional activity and sunlight. Throughout the animal kingdom oxidation processes are fundamental to tissue activity and discharge of energy under the influence of stimuli from the external world, resulting in the production of fatigue products and a degree of exhaustion of potential energy which is capable of recuperation by rest. The normal conditions of sunlight and oxidation processes have been habitually juxtaposed in the evolution of the animal kingdom. While at the end of the day till dawn there is a lowering of oxidation processes in response to absence of environmental stimuli, there is a storage of potential energy. The fall in potential energy at the end of the day has in the long procession of ages been associated with a desire for sleep. This manifests itself especially by an inability to keep the eyes open, and there is a feeling of fatigue in the elevators of the eyelids which tend continually to droop and shut out the light. R. Semon has shown that habit and memory are based upon the same fundamental principles. When two conditions are juxtaposed in time and place either one will revive the other. Thus, if we represent C as sleep, A as night, B fall of potential energy and fatigue, sleep is induced habitually by either A or B. Probably B is the more important factor in determining the desire for sleep. Consequently, when persons have to work by night and sleep in the daytime, they experience a fall of potential energy at the dawn and a desire for sleep in the day.

According to Claparide we must look upon sleepiness as occurring not because there is an actual exhaustion of the brain, but in order that it may not be reduced to that extremity. Every normal child, like the adult but in a less degree, possesses a store of nervous and muscular energy over and above that which it requires in ordinary conditions of life; and this statement is borne out by all the known facts, experimental and otherwise, concerning mental and bodily fatigue. The reserve energy certainly varies in amount in different individuals; it is intended only for emergencies and should not be habitually drawn upon. The sense of fatigue and the desire for sleep may be regarded as the protective and the instinctive guardians of this reserve of nervous energy. Both give warning that the reserve is about to be drawn upon, and if the warning is continually allowed to pass unheeded, exhaustion of the highest inhibitory function of the brain cortex ensues, and associative memory, thus left unchecked, permits a continuous flow of ideas, resulting in mental excitement and sleeplessness. A vicious circle tends thus to become installed which, if not broken, leads to bankruptcy of nervous potential, with permanent mental irritability and lack of mental energy.

THE ADVENT OF SLEEP.

Drowsiness and somnolence are induced by many external conditions of the body even during the daytime, for example, a heavy meal at mid-day with alcoholic beverages. It is a mistake to think that alcohol acts directly as a stimulant—its action is narcotic, but it produces an apparent stimulating effect by its narcotising action on the highest level of the brain, viz., inhibitory control, and if the environmental conditions are not acting as an exciting cause, loosening association and flow of ideas, then alcohol acts as a narcotic and produced somnolence, drowsiness, and sleep. Even a heavy meal with alcohol tends to drowsiness, blood is derived away from the brain. A hot, stuffy atmosphere in which there is excess of CO_2 assisted by an uninteresting discourse or lecture delivered with a monotonous tone and rhythm induces somnolence. One tries to keep one's eyes open and the head up and to attend, but in spite of conscious effort the eyelids droop or close, the jaw drops, and the head falls forward on the chest or lateral-wards or backwards. We may become partially conscious, or partly conscious if something happens to vary the monotonous drone, and light up again the lamp of attention and awareness. Is this sleep a sort of protective vital reaction, the first signs of which are those connected with the tonic contraction of head and eye muscles due to failure of proprioceptive kinæsthetic and postural stimuli that tell of spatial relation regarding our own position in the three dimensions of space, and relation to objects in the world around? The drooping of the eyelid and closure to the light stimulus, combined with relaxation of the head and neck muscles which extend to the rest of the skeletal muscles, is probably due to the lowering of the labyrinthine stimuli which tell us of the position of the head in the three dimensions of space, and also have a marked influence upon the tone of all the muscles of the body as well as the head and neck. Now, the eye muscles and the head and neck muscles are associated in their action and the successive series of proprioceptive postural and kinæsthetic stimuli arising from them, lead to our consciousness of environmental happenings in the three dimensions of space. The upward and downward movements of the eyes are related to vertical space, the lateral movements to horizontal space, and convergence, associated with accommodation by the ciliary muscle, to depth. There is an intimate association of the ocular nuclei and the vestibular nuclei by the posterior longitudinal bundle. Failure of the proprioceptive stimuli from the head and eye muscles would produce a loss of the principal element of consciousness—viz., the spatial relations of the individual to the world around. If, then, there is a part of the brain which has control over this elemental function of consciousness, common to all animals, it will be by its inhibitory influence, primarily on the tonus of muscles of the head and neck and eyes. The proprioceptive and labyrinthine stimuli of sufficient intensity to maintain the eyes open, and the lower jaw and head up against the force of gravity, would eliminate the principal tributary to the stream of consciousness. The cessation of this tributary to the stream of consciousness may be regarded as a device of Nature to put the body in the best position for unconscious quiet of the mind and bodily rest, viz., the prone position when other important sources of anti-gravity stimulus are removed. Sherrington has shown in the Linacre Lecture, "Problems of Muscular Receptivity," that the stimulus which is the source of reflex standing is one acting on the receptors of those limb muscles which are themselves executants of posture. They are those which keep the head and neck from sinking, the trunk straightened, and the spine supported, the limbs from yielding and folding under the superimposed weight of the body. He showed in the decerebrate animal the postural act of standing can take place with the skin nerves divided. Now, in the "knock-out blow" cn the point of the chin the man falls down and is unable to rise in the allotted ten seconds, and he is unconscious, or only semi-conscious, for seconds. What has happened to cause this annihilation of the reflex standing postural condition? Shock to the semicircular canals transmitted through the articulations of the lower and upper jaw, causing a loss of tonus in all the muscles of the body. Dr. Golla long ago showed that a person placed in the rotating chair, owing to labyrinthine disturbances loses his knowledge of spatial relations and may even fall off the chair unconscious. These neuronic systems connected with proprioceptive ocular and labyrinthine functions exist in the mesencephalon and pons where inflammatory changes are especially met with in encephalitis. May not the lethargic condition met with in this disease be due to their failure to function properly?

During natural sleep, however, the whole central nervous system is resting, indeed, the vital biochemical katabolic processes of the whole body are lowered, for there is less oxygen used, less carbonic acid produced, and less heat. Goltz's dog that lived for a year, after the whole of his cerebral cortex had been removed, slept. There are various degrees and varieties of unconsciousness; they are: (1) light sleep; (2) sleep disturbed by dreams; (3) sound sleep —but not so sound that the individual cannot be aroused; (4) coma, a deep sleep from which the patient cannot be aroused; but I do not intend to say anything about this last condition.

DREAMS.

Sleep disturbed by dreams is unrefreshing, especially if the dreams are terrifying. Kant said:—

> "I rather suppose that ideas in sleep may be clearer and broader than even the clearest in the waking state, for man at such times is not sensible of his body. When he wakes up his body is not associated with the ideas of sleep, so that it cannot be a means of recalling this former state of thought to consciousness in such a way as to make it appear to belong to one and the same person."

So that a neurasthenic who says that he does not dream, yet wakes up unrefreshed by sleep, probably has been dreaming and actively using up neural energy. Dreaming can be accounted for in many instances by external excitation, as the following experiments related by Verwoorn show: a man who was asleep dreamt he heard the firing of guns when small pebbles were thrown against the window-pane. Another, who, when asleep, was sprinkled with a few drops of water, dreamt of storm and rain. Again, another who had placed under his nose a perfume that he had brought from Egypt, dreamt that he was in the bazaar at Cairo and entered the shop where he bought the perfume. When I had fever (? typhoid or influenza) I had two dreams which illustrate this peripheral excitation in the production of terrifying dreams with a great magnification of the effect of the excitation, probably due to the loss of inhibition through the toxin on the highest level of the cortex. I had a pretty marked pharyngeal and nasal catarrh. I dreamt that my nose was swelling inordinately until it became an elephant's trunk, and then in my delirium I saw hundreds of trunks. Another dream was even more terrifying, and owed its origin to a peripheral cause. The country practitioner who attended me gave me a big dose of antifebrin to bring down the temperature; it fell rapidly from over 104° to subnormal. I dreamt I was a prone marble statue undergoing liquefaction. I awoke cold and bathed in perspiration, and for some few moments I hardly realised I was alive and I was unable to move or shout for help. Everyone knows how an indigestible supper will produce nightmare. Is it not told in the "Ingoldsby Legends" about the young man "who had something on his chest, Mother," and with the conclusion it was "that confounded cucumber I've eat and can't digest, Mother." The war taught us how true was the philosophy of Lucretius, who, in "De Rerum Natura" says:—

> "And generally, to whatever pursuit a man is closely tied down and strongly attached, on whatever subject we have previously much dwelt, the mind having been put to a more than usual strain in it; during sleep we for the most part fancy that we are engaged in the same; lawyers think that they plead causes and even draw up covenants of sale, generals that they fight and engage in battle, sailors that they wage and carry on war with the winds. We think that we pursue our task and consign it when discovered to writings in our own native tongue. So all other arts and pursuits are seen for the most part during sleep to occupy and mock the minds of men."

Lucretius next calls attention to the evidence of dreams in animals:—

> "And often during soft repose the dogs of hunters do yet all at once throw about their legs and suddenly utter cries and repeatedly sniff the air with their nostrils as though they had found and were on the tracks of wild beasts."

In another passage Lucretius says :—

> " Again the minds of men which pursue great aims under *great emotions* often during sleep pursue and carry on the same in like manner ; kings take by storm, are taken, join battle, raise a loud cry as if stabbed on the spot."

In Shakespeare there are two passages which may have had their source of inspiration in the " De Rerum Natura " of Lucretius—viz., the speech regarding Queen Mab by Mercutio and that of Lady Percy to Hotspur. As Lucretius says, a man dreams of whatever pursuit he is closely tied down to ; during the Great War the soldier dreamt that he was in the trenches fighting Germans, or he heard and saw the shells bursting, shouted in his sleep, and awoke with a start. How truly Shakespeare describes this when he says :

> " Sometimes she [Queen Mab] driveth o'er a soldier's neck,
> And then dreams he of cutting foreign throats,
> Of breaches, ambuscadoes, Spanish blades,
> Of healths five fathoms deep ; and then anon
> Drums in his ear ; at which he starts and wakes,
> And, being thus frighted, swears a prayer or two
> And sleeps again . . . . . . "

(In the quarto 1597 edition the text had " mines and countermines " instead of " Spanish blades," which seems singularly appropriate just now.)

In Lady Percy's speech to Hotspur there is the following passage :—

> " Why hast thou lost the fresh blood in thy cheeks ;
> And given my treasures and my rights of thee[1]
> To thick-eyed musing and cursed melancholy ?
> In thy faint slumbers I by thee have watch'd
> And heard thee murmur tales of iron wars :
> Speak terms of manage to thy bounding steed,
> Cry, ' Courage ! to the field ! ' And then hast talk'd
> Of sallies and retires ; of trenches, tents."

My experience accorded with this statement of Mr. Curdy. Numbers of officers and men admitted to the Neurological Clearing Hospital suffering with anxiety neuroses, contemplation and fear, had lost sexual desire.

The war also taught us that sleep disturbed by terrifying dreams was associated with disorder of the endocrine system of glands, manifested by signs of Graves's disease and high blood pressure, which disappeared when the terrifying dreams ceased. Freud has emphasised the importance of the analysis of dreams in ascertaining the existence of a repressed fear complex. According to my war experience too much stress was laid by Freud and his followers on fear complexes related to sex functions, although the great importance of these must be recognised and cannot be disregarded in relation to causation of the psychoneuroses, but it is not my intention to discuss this question further.

LETHARGY CAUSED BY DISEASE.

The cause of the drowsy condition, somnolence, and lethargy met with in certain diseases of the brain —e.g., lethargic encephalitis, sleeping sickness due to trypanosomiasis—has aroused a new interest in the question whether sleep is not a vegetative function which has a functional representation in the central nervous system in a situation where the regulation of metabolism exists. In sleeping sickness there is a perivascular lymphocyte infiltration affecting not only the cortex but especially the medulla, mid-brain, and basal ganglia. I always thought that the lethargy and the weakness and ready fatigability by which a patient would become drowsy and somnolent after a few minutes' conversation was due to a failure of oxygen-supply to the cortex by the stasis of blood and cerebro-spinal fluid. Whereas, in lethargic encephalitis it is the mesencephalon, the pons, medulla, and the basal ganglia which are especially affected, in general paresis, when the cortex, and not these structures, is involved, you do not get this lethargic condition. I have already suggested a reason for sleepiness by lesions of the pons and mid-brain interfering with ocular proprioceptive and labyrinthine stimuli, which are essential for consciousness of spatial relations of the world around.

Various authors have put forward other views regarding the lethargy of encephalitis. For example, Buzzard thought it might be due to intraventricular pressure of accumulated cerebro-spinal fluid owing to the œdema of the mesencephalon interfering with the flow of fluid from the lateral ventricles through the aqueduct of Sylvius ; interruption of sensory impulses to the thalamus (Gayet) ; disturbance of the muscle tonus (Marinesco), and to some extent also of endocrine secretion ; but against this there is no evidence of any affection of thyroid or suprarenal glands. Whether the pituitary is affected or not I do not know. Van Economo postulates the theory of a sleep centre in the neighbourhood of the oculo-motor nuclei.

According to Prof. Wimmer the symptoms belonging to the " hypophysis syndrome," such as adiposity or cachexia, polyuria, polydipsia, glycosuria, and morbid changes in the sexual organs and in their functions, constitute the main features of vegetative disturbances in chronic encephalitis. But a number of clinico-anatomical and experimental investigations have, however, unsettled our views as to these hypophysis syndromes. For the experiments of Roussy and Camus have shown that in the basal grey matter of the brain just above the hypophysis—hypothalamus, the tuber cinereum, and infundibulum—there is a series of vegetative centres (cerebral control of sympathetic), and a lesion here, although the pituitary body is not touched, may give rise to hypophyseal symptoms— viz., an adiposo-genital syndrome, polysarcia, atrophy of testes, apathy, somnolence, and occasionally diabetes insipidus.

INSOMNIA.

Insomnia is a troublesome symptom occurring in most acute and chronic diseases or illnesses. It may be due to pain, to irritating cough, fever, cerebral excitement arising from toxic delirium, organic brain disease, anxiety neuroses, psychoneuroses, and psychoses. A prevalent form of insomnia for which one is frequently consulted, and to which I will particularly call attention, is a condition found especially in modern urban life and may almost be regarded in itself as a malady. It is a powerful factor or contributory cause in the production of neurasthenia and of a nervous breakdown usually said to be due to overwork, but it is not so much overwork as anxiety, worry, and mental conflict, or a repressed fear complex, the nature of which may be revealed to the sympathetic physician who is able to gain their confidence.

Charles Darwin in his " Life and Letters " refers to his father, who was a physician at Shrewsbury, as the wisest man he ever knew. He was known as the " father confessor," for numbers of patients came to him suffering from what they believed to be bodily diseases but which were really due to fears, which he was able, by a sympathetic understanding and wisdom, to dispel from their minds or help them to fight against. I always ask my patients : " Have you any financial worry ? Have you any domestic worry ? Have you any cause of anxiety ? " And I explain to them that it is worry and not overwork in most cases that causes insomnia, and that as soon as sleeplessness becomes habitual trifling troubles are magnified and cause depression. Where there is a latent innate potential cause of the psychosis these conditions of worry and anxiety producing insomnia are apt to set up delusions of a persecutory nature. Hence the necessity of taking early measures to prevent habitual insomnia, even if one has to start with drugs. But the great and important matter is to endeavour to restore as soon as possible the habit of normal sleep. To do this you have to find out what the daily life of your patient has been, what are his real anxieties, and how they can be alleviated. He may suffer with dreams which may be a clue to the fear complex which is the hidden cause of his psychoneurosis. What should we do for such a neurasthenic patient? The first thing is to make a thorough physical examination. For so many of these patients have functional derangements of a distressful nature which lead them to believe they are suffering from a bodily disease—for example, they believe they are impotent; they have heart disease; gastric disease; or an organic disease of the nervous system; or that they will become insane. They liken their symptoms to some friend who has recently died of tumour of the brain or general paralysis. Be cheerful and look cheerful, and assure them that, having made a careful physical examination, you are sure that there is no organic disease and no probability of it arising. These neurasthenic people, men and women, are eminently open to suggestion, and you will inspire hope by being cheerful to them. They complain of weariness, inability to concentrate, failure of memory, of being easily fatigued; they suffer with indigestion and constipation. Explain to them that these are only signs of lack of nervous energy flowing to the voluntary and involuntary muscles, due partly to the insomnia, and that with the restoration of natural sleep habit all these signs and symptoms which have alarmed them will disappear. Inquire into their domestic, financial, and occupational capacities to carry out your suggestions, for you will only increase anxieties if you propose impossible conditions of treatment. Sunlight, fresh air, and occupation with interest in the open air—for example, golf—should be recommended: the value of this game to the business and professional man is that he cannot introspect, he must make a continual series of fresh mental adjustments; he is taking moderate exercise in the open air, takes his own time and does as much or as little as he feels inclined. Walking, motoring, and fishing are not so good because they do not break the train of anxious thought. I am often asked "Ought I to sleep after lunch?"—I say sleep is a protective instinct, and to yield to the desire is natural even if it comes at an unnatural time. Attention should be directed also to all those conditions of comfort and quiet which facilitate sleep and which you all from experience know.

---

[1] Mr. Curdy, in discussing the Anxiety Neuroses of Soldiers, said : " The man who is visited by his wife or his sweetheart is a disappointment both to himself and his visitor in that it is impossible for him to give any proof of his affection. This finds expression in a manifestly obvious way through the symptoms of impotence, which, is so far as I have been able to learn, universally present in the anxiety state, either as such, or in the form of its equivalent lack of erotic feeling."—" War Neuroses," Psychiatric Bulletin of New York, July, 1917.

TREATMENT BY DRUGS.

Pain is best relieved by morphine, either hypodermically combined with atropine, or by mouth. In some cases morphia combined with hyoscine (¼ gr. of the former to 1/200th or 1/100th gr. of the latter); for the lightning pains of tabes, veronal and aspirin may be given, but pyramidon (5 to 8 gr.) is more effective. For sleeplessness due to toothache and trigeminal neuralgia, I have found useful croton-chloral-hydrate (5 to 10 gr.), with tincture of gelsemium (♏5 to 15), repeated in four hours if no relief. Veramon 6–15 gr., according to the severity of the pain, has been recently recommended.

Hypnotics employed for insomnia are numerous.

"*General Requirements for Insomnia.*—1. They shall produce sleep of sufficient depth without secondary action, especially on respiration and circulation. Those which contain Cl are more depressant on respiration or circulation. 2. Sleep shall be quickly induced—e.g., within half an hour. This depends upon the ease with which they are dissolved and absorbed. Tabloids or tablets should always be crushed—otherwise give powder in cachets. 3. The action should be of sufficient duration—viz., six to eight hours. 4. Rapid and complete excretion or conversion into a harmless product; otherwise there will be a tendency to accumulative effects. 5. Prolonged use of same drug should be avoided for two reasons: first, because of cumulative effect and tolerance requiring increased dosage; second, habit formation."[2]

If sleeplessness has its origin in mental strain and unrest, anxiety, mental conflict, or psychic causes, chloral hydrate or some other hypnotic of the fatty series—viz., paraldehyde, chloretone, chloralamide, or the coal-tar derivatives—e.g., sulphonal, trional, or one of the barbituric acid series: veronal, dial, luminal, bromural, dormiol, adalin may be employed. The great advantage these drugs have over morphine is they do not cause constipation, and the danger of becoming habituated to them is less. The action of chloral hydrate is similar to chloroform but more lasting. Sleep is quiet and deep, often accompanied by dreams: dose 10 to 20 gr. This drug is often combined with an equal quantity of a bromide salt, and in mental cases with equal quantity of bromide together with cannabis indica and hyoscyamine. In cases where there is an idiosyncrasy, chloral is liable to produce urticaria, erythema, and other skin eruptions. For ordinary sleeplessness chloral and veronal, or its sodium salt medinal, are frequently used as good remedies in the delirium of fever—for example, typhoid, where, owing to its action on the heart, chloral had better not be used, nor in cases where heart and lung diseases exist. Chloralamide, 1·5 g. equal 1 gr. of chloral, is a useful drug. Adalin is a hypnotic of moderate strength, often acting well; it has the advantage of being quickly eliminated. Bromural is a hypnotic and sedative, weak in action, but has very little toxicity; 5-10 gr. in tablets is the dose. Paraldehyde, if it were not for its unpleasant taste and the odour of the breath afterwards would be more extensively used. It is safer than chloral because there is no action on the heart or respiration; 1–2 drachms or more may be given in cases of typhoid fever and cardiac diseases. It is especially useful in mental diseases where prolonged use of hypnotics may be necessary. It may be given with 5–10 gr. of veronal, medinal, or trional to prolong the sleep. Dormiol is a combination of amylene and chloral. It is recommended on account of its rapid action and is in most cases reliable. It is given in capsules 8–15 gr. Veronal, diethyl-barbituric acid, is apt to be cumulative like sulphonal, and should not be given for more than a week. Luminal belongs to the barbituric acid series, but the ethyl group C_2H_5 is replaced by C_6H_5, phenyl ethyl. It is especially suitable for cases of sleeplessness where the disease takes the form of night attacks. It is much used for epilepsy, ½ gr. to 2 gr. twice or three times a day. Dial, diallyl barbituric acid, is used in many of the mental hospitals and I have found it useful as a hypnotic. But like other drugs of this series it is not well to continue its use for long: the dose is one tablet of 1½ gr. to one and a half to two tablets. Most of these hypnotics in powder or tablet form should be given in hot milk or some other hot fluid half an hour before bedtime. But it should always be our main endeavour to restore the habit of normal sleep, by the ascertainment of the causes of sleeplessness and removal thereof.

DAVID LEWIS EPILEPTIC COLONY.—At the annual meeting, held in Manchester, Dr. Alan McDougall, the director of the colony, emphasised the importance and success of the early treatment of epilepsy. In the congenial surroundings of the colony a considerable number of chronic sufferers had ceased to have fits, and had returned to the outside world. If patients entered at an earlier stage of their illnesses, he said, the results would be better still. Many children who were in the residential school of the colony ceased to have fits, and were now back at their homes and earning their own livings. In his own home among his healthy brothers an epileptic child usually became peculiar, spoilt, and unpleasing, and remained uneducated. At a colony the children were not made to think themselves invalids or abnormal. It seemed probable that the determining factor in the beginning of epilepsy in a child was often some untraced mental irritation in the child's circumstances. The mere removal of the child to the congenial atmosphere of a residential epileptic school apparently was often enough to end the trouble, provided that the delay had not been allowed to set up the fit habit. The first fit should be the indication for a child's immediate removal. In view of the importance of treatment of epilepsy in the early stage of the disease the committee have decided to proceed with the erection of a new home for 32 boys—the provisional estimate of the cost being £18,000.

THE USE OF SUCTION IN SURGERY.

BY NORMAN C. LAKE, M.D., M.S., D.SC. LOND., F.R.C.S. ENG.,

SURGEON IN CHARGE OF OUT-PATIENTS, CHARING CROSS HOSPITAL.

UPON many occasions in the history of surgery the use of various contrivances for producing suction has been advocated and tried, but with the exception of one or two important instances such methods have rapidly been abandoned and the apparatus discarded. These exceptions are the suction apparatus known as an aspirator used in dealing with pleural effusions; the syringes used for aspirating abscess cavities and withdrawing blood and other fluids for investigation; and the method of producing passive congestion introduced by Bier. To these may also be added the use of Cathcart's apparatus for draining the bladder after prostatectomy, although this has now been largely superseded by the use of the Irving "tortoise." Of the addition of such apparatus to the armamentaria of the surgeon, or of their use in the ordinary technique of general surgery, there is, however, little sign. The reasons for this apparent indifference to an innovation which is not without its advantages are probably not far to seek. Most of the appliances so far invented have been rather clumsy and, although perhaps satisfactory for particular work, peculiarly unsuitable for general surgery.

A more weighty reason, however, is the fact that they have been regarded as cumbersome instruments, perhaps rendering the surgeon's work a little more easy, but quite devoid of any higher value. Indeed, up to the present suction in general surgery has been condemned as only a complicated substitute for an ordinary swab. There has been, besides, the natural antipathy to adding to the already overburdened instrument cabinet. Complexity, however, is in itself of no real disadvantage if the results obtained are satisfactory. The modern operating cystoscope and the Albee electro-operative bone saw are sufficient instances of this. The use of suction does unfortunately imply additional apparatus, but if it can be proved that it is of convenience to the surgeon, and, what is much more important, that it is a real advance in technique intimately affecting results, then this is of little importance.

Fields of Usefulness for the Suction Apparatus.

The essential characters of a suitable apparatus will be considered later, but at first it must be questioned whether it supplies an actual need. As a type case the perforation of a duodenal or gastric ulcer may be taken. Here the aim of the surgeon may be summed up as follows: The perforation must be closed, the abdominal cavity emptied as thoroughly as possible of its contents, and, since the patient is often profoundly shocked, the whole must be performed as rapidly as is consistent with thoroughness. The author has found during the year the apparatus has been on trial that its use not only shortens the time taken considerably, but that the peritoneal cavity is emptied more completely than by any other method, with the exception perhaps of massive lavage, which for many good reasons has become almost obsolete. In such cases, therefore, the advantages of suction are established, but they by no means end there. The modern tendency of abdominal surgery is to avoid drainage except in cases of overwhelming infection, and to rely very largely upon the general resisting powers of the peritoneum. The success which attends this method of treatment depends upon two factors. In the first place as little residual infective material must be left behind as possible, and in the second the endothelial lining of the peritoneum must be preserved intact over the greatest possible area. Both of these desiderata are much more nearly achieved when suction is employed than by the common method of swabbing. Suckers can be designed which damage the endothelial lining scarcely at all, and at the same time rapidly empty the cavity of every drop of contents. Where large portions of solid food have escaped this statement may not be strictly true, but such cases are few and far between in these days of early diagnosis, and even then suction will be more effective than other methods. Surgical instinct shudders at seeing a large cotton swab pushed into the pelvis, twisted around, and then withdrawn, bringing with it portions of detached endothelium and much valuable lymph.

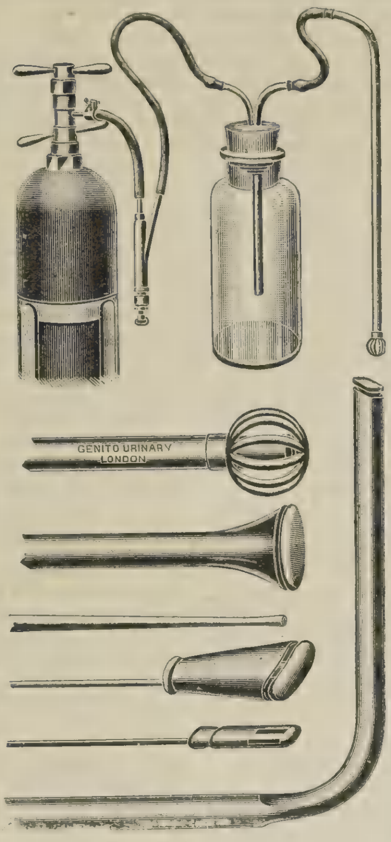
The removal of and damage to endothelium not only diminish the immediate resisting powers of the peritoneum, but also lead to the formation of adhesions which may ultimately cause serious symptoms.

Experiments which have been recently performed in America and elsewhere upon the formation of adhesions prove conclusively that damage to the endothelial coat is the most important point in their production, and that conversely as long as the endothelial coat remains reasonably intact there is little fear of their formation. This explains the failure of many of the methods of preventing adhesions, for where the endothelial coat is already lost over large areas nothing appears to be of any avail, while some of the materials used—i.e., ether—were in themselves capable of destroying this coat. In actual surgical practice prolonged and chronic infections, and the irritation caused by foreign bodies (the chief of these being drainage-tubes) are the common causes. Inasmuch as suction reduces the number of cases in which drainage is necessary, leaves the endothelial lining intact, and empties the abdomen of foreign and infective material most thoroughly, it is hoped that its use will diminish the mortality and very largely prevent serious sequelæ.

In other realms of abdominal surgery it will be found equally useful. In the case of rupture of an ectopic gestation the more fluid portions of the blood can be easily removed without disturbing the general abdominal contents; the method of removing clot by suction will be again referred to when the apparatus is described. Within the last year it has been suggested that in such cases the blood should be collected and after suitable treatment returned to the patient by infusion. The author has not had a case in which he thought this advisable, but by the use of a suction apparatus its performance could be carried out in a perfectly aseptic manner without exposure even to air. In cases of suppuration about the appendix or in the pelvis the pus can be aspirated in the early stages of the operation without fear of spreading infection. Its use is not limited, however, to emergency or infected conditions; in operations upon the gall-bladder and stomach there is frequently some leakage of bile and oozing of blood over the field of exposure. A small sucker can be attached to the blade of a retractor down to the kidney pouch which, without disturbance of the wound, will periodically remove all this. In bladder operations, too, it can be similarly attached, and will keep the field clear of urine and blood, thus reducing the necessity of harmful swabbing to a minimum. As another instance, if it be thought advisable the chest can be rapidly emptied completely of pus after resection of a rib without disturbing or distressing the patient. In bone and joint surgery, indeed in any case where there is oozing or exudation and it is essential to keep the field dry with a minimum of trauma, the same applies. The special case of surgery in and about the mouth must be dealt with in greater detail.

The introduction of insufflation anæsthesia has relieved the surgeon's anxiety very considerably in such cases, but it is not always available, and in any case has no effect on the collection of blood in the mouth except to prevent it from entering the larynx. If a flexible sucker, such as is described later, be introduced into the naso-pharynx through the nose the whole throat can be kept dry by its occasional use with no inconvenience to the surgeon whatsoever. Every surgeon who operates upon cleft palates at all frequently knows that the bugbear of these operations is the constant interruption for swabbing away blood, and that these repeated swabbings damage the freshly cut edges of the palate to such a degree that I have known a very experienced operator attribute a failure of union to this cause alone. The advantages to be derived from the use of a suction apparatus in these operations must be seen to be believed.

The author has had the opportunity of performing cleft palate operations for several years, and has no hesitation in saying that since the introduction of suction the results obtained have been very much improved. In suitable cases the whole operation can be conducted without the use of a single swab, and if it should be necessary they are used merely to keep up pressure and need not come into contact with the freshened surfaces. The operation proceeds rapidly without interruptions, and there is no risk of blood being either inspired or swallowed. Incidentally, the apparatus has also been found of value in cases of post-anæsthetic vomiting, to empty the pharynx quickly without producing further gagging. In cerebral surgery, too, by the use of specially designed suckers the field can be kept free of blood with a facility unknown when other methods are employed, and the surgeon's fixity of vision is not interfered with, a point of great importance in many rather delicate operations.



The illustration shows the pump as attached to the gas cylinder, together with collecting bottle and sucker. The different types of sucker heads are shown enlarged below.

Essential Characters of a Suitable Suction Apparatus.

From a consideration of the above it will be seen that there can be no doubt as to the surgical value of the method, and we must now return to a consideration of the essential characters of a suitable apparatus. These can be summed up by saying that it must, as far as is possible, be universally useful for all types of cases and at any place, so that it must not only be easily portable but the power should be obtainable without difficulty, and the number of sucker heads, at least for general purposes, should be reduced to a minimum. An apparatus of the type of Potain's aspirator worked by a hand pump, while satisfactory for its special purpose, would obviously be of little use for the continuous suction required in general surgery, and any hand or foot operated pumps, if of a size suitable for continuous suction, would be clumsy to handle and not easily portable. The most popular suction pump at the present time is a reciprocating or rotary one worked from a small electric motor. These are certainly very efficient, but are only available where the correct type of current is laid on, the weight of the accumulators or transformers and resistances otherwise necessary being prohibitive.

This is really, however, not a very great disadvantage, since there are few places nowadays without an electric supply. A much greater disadvantage is the fact that the apparatus is of considerable size and weight, and in addition all those at present designed run with an excessive amount of noise and vibration. The vacuum produced by these pumps is comparatively high, and tends to rise when there is any obstruction to the sucker head. This at first sight may appear to be of advantage, but when it is considered that important structures may be drawn into the head with excessive pressures and so damaged, it will be recognised that an apparatus producing a strictly limited but nevertheless sufficient pressure would be more valuable.

Description of the Apparatus.

It was for these various reasons that the author devised a suction pump on a totally different principle, for which the following advantages are claimed. It is very small, weighing together with attachments but six ounces, and can be carried in the operating bag with the actual suckers themselves. Worked from cylinders of compressed gas, either oxygen, nitrous oxide, or air, it is vibrationless and quiet in action.

The question of convenient power was a difficult one. Something after the nature of the ordinary filter pump working off the water main would certainly have served the purpose, but it is rare for such water pressure to be obtainable in the actual operating theatre, and to have led the suction tube from the adjoining sterilising room would have necessitated a great length of inconvenient tubing and considerable loss of power. In addition, its use in the rooms of a private house would be precluded in most instances. An oxygen cylinder is, however, an essential part of the equipment of every operating theatre, whether in hospital or nursing home, and in the rare cases where it is not likely to be available there is little difficulty in transporting a small cylinder for the purpose. In cases of emergency it is well to remember that these are stocked by most chemists, or one of the anæsthetist's nitrous-oxide cylinders can be used. Where cylinders of compressed air are available they will, of course, be used in preference, but at present compressed oxygen is not only easier to obtain but, strange to say, cheaper. The actual power is obtained from the velocity and expansion of the issuing gas. This is led via a short piece of pressure tubing to a small nozzle situated just behind the narrowed orifice of a small cylindrical chamber, both the internal and external leads to the orifice being parabolic in contour.

Partially blocking the orifice is an obturator also parabolic in shape. The issuing gas therefore, by its momentum and expansion, creates a negative pressure in the chamber, a certain degree of turbulence being produced at the orifice. From the chamber a side tube is connected to the collecting vessel and via this to the sucker itself. It will be seen that there is a maximum vacuum produced which is constant for fixed size of nozzle and orifice, position of obturator and pressure of issuing gas; and that this vacuum cannot be exceeded even although the sucker be completely blocked as long as these factors remain constant. This is a unique feature of a pump of this type and acts as a kind of safety-valve, automatic in its action, preventing important structures being damaged by working their way into the end of the sucker. In an experimental model various sizes of nozzles were tried, and it was found that the smallest nozzle would give a negative pressure of nearly 300 mm. of mercury, while at the same time being sufficiently economical of gas. Considerably greater negative pressures than this can be obtained by the use of larger nozzles with some loss in economy, but in practice it will be found that the vacuum given above, which equals between six and seven pounds to the square inch, is ample for all ordinary purposes. In the standard model the nozzle and the obturator are both adjustable. The general efficiency of the pump is extremely sensitive to slight variations in the positions of these, and for this reason, if the pump is to be used on fixed pressures, it is advised that a model with fixed nozzle and obturator be obtained. In other cases the maximum position can be obtained by trial, a negative pressure mercury or other manometer being attached to the side tube, the nozzle and obturator can then be fixed in position by the lock nuts provided. Once adjusted, there being no moving parts, no further attention is required. If by an oversight the collecting bottle should become so full that its contents are sucked over into the pump itself, the latter may be easily cleaned by unscrewing the whole of the front end which includes the obturator when the interior is well exposed. If desired, nozzles with varying apertures from 0·5 mm. to 1·3 mm. can be obtained; the larger sizes are rarely required, however, and the standard nozzle is 0·5 mm.

It should be mentioned here that although this pump bears a general resemblance to the well-known boiler injector, the principle underlying its action is essentially different. In the steam injector the negative pressure is obtained by the sudden condensation of the issuing jet of steam as it meets the incoming water. Such a pump will work at comparatively low pressures and will pump against a pressure greater than its own. In the present pump no condensation occurs, the suction being obtained solely by the momentum of the expanding gas. Very high pressures, in the region of 100 atmospheres, are therefore necessary in order to obtain sufficient velocity of flow, and when the pressure falls much below 30 atmospheres the pump loses seriously in efficiency. For this reason the apparatus must work directly off the gas cylinder without, of course, the intervention of any reducing valve. The whole appliance may be attached to the cylinder in its stand, and if the milled wheel of the needle valve be covered by a sterile towel it can easily be worked as required by the surgeon himself, the actual suckers and the collecting rubber tube being the only parts that need be sterilised. In addition to the orthodox method of working the pump given above it can also be attached to the ordinary nitrous-oxide-gas apparatus with foot control, and finally in large operating theatres where high-pressure steam is laid on it may be permanently attached, but in such a case, as the pressure available is much lower, a special large nozzle must be used. Between the pump and the actual sucker is placed a receptacle for collecting the fluids withdrawn. This should be as small as possible consistent with its ability to hold a reasonable quantity without constant changes being necessary. Considerable variation occurs according to the character of the work. For cleft-palate cases a small bottle holding less than a pint will be found sufficient, but for abdominal and bladder work the capacity should not be less than a quart.

A large amount of attention has been paid to the design of the suckers themselves. For the simplest types of work, such as the removal of thin fluids from open cavities with rigid walls, an ordinary piece of rubber or other tubing is all that is necessary. For the majority of cases, however, including abdominal and bladder operations, specially designed suckers are essential if damage to surrounding structures and constant blockage of the tube are to be avoided. A universally useful type of sucker head is that shown in the illustration. All the surfaces are made exceedingly smooth and the suction is applied around the sides only of the expanded head. The tendency for bowel or mucosa to be drawn into the sucker is therefore minimal. The tube is curved above to form a suitable handle for manipulation, and upon the convexity of the curve is an aperture which while the pump is working is closed by the finger.

In the event, however, of there being any tendency for tissues to be drawn into the sucker, and the only tissue which it has been found by practice is likely to do this with specially designed suckers is very thin omentum, the finger is immediately removed from the aperture, thus releasing all negative pressure on the end of the instrument. The same design is made in oval shape for use in narrow cavities, and in flattened form to replace one of the blades of a bladder retractor. Made with a flexible stem it can be moulded to fit any sort of wound, while in small sizes it forms the most suitable sucker for cleft palate cases. For abdominal work, where there are larger quantities of fluid present, the cage sucker head will be found more satisfactory. For clearing blood and fluid from the naso-pharynx a small flexible and flattened head is required, while for operations where the exposure is very limited, such as mastoids and operations upon the base of the brain, Gasserian ganglionectomy, &c., a very fine sucker is demanded. The aim, however, has been to reduce the number of sucker heads required to a minimum, and it will be found that for general work the first type described is sufficient.

In the accompanying illustration the cage and universal suckers are shown first and second. The third is a fine probe-ended sucker made of flexible metal so that it can be bent to enter any small cavity without interfering with the line of vision. It will be found particularly useful in operations upon the brain, but owing to the small calibre care has to be taken that the blood does not coagulate in the orifice. In both the fourth and fifth types the rigid handle is replaced by a flexible metal probe attached to the head. In this case the stout rubber collecting tube is passed over the probe and attached to a suitable rim on the head. The probe can now be bent to accommodate itself to any shaped wound and will carry the rubber tube with it. No. 4 is especially useful in operations upon the gall-bladder, where it can be made to lie well out of the way in one corner of the wound. No. 5 is designed to be passed through the nose and to lie in the naso-pharynx during operations upon the mouth, the probe carrying the rubber tube being bent around the margin of the nostril to hold it in situ. The last illustration is of a sucker designed for use in operations about the base of the bladder and is so shaped that it at the same time acts as a retractor. The following quotation from a recent article upon carcinoma of the prostate by Mr. Clifford Morson illustrates the value of suction in such cases: "Until recently I have been hampered by the blood welling up at the bottom of the wound and obscuring my view, but this obstruction has been overcome by the use of Lake's suction pump. This instrument not only evacuates the blood as it collects, but by a slight modification can be used as a retractor."

In entering into further details concerning the use of these suckers it must be remembered that the real problem is not the suction of thin fluids, but of such materials as blood and thick pus, often containing large flakes of lymph, and it would be as well to state without delay that there are some varieties of pus and of blood-clot which can never be removed by suction. The reason for this is fairly obvious, for at most the atmospheric pressure of 15 lb. to the square inch is available even with a perfect vacuum, and most of the pumps for producing suction fall short of this by a big percentage. The author has conducted experiments which show that a pressure of 15 lb. to the square inch is not sufficient to move old blood-clot or lymph along tubes of such size as can conveniently be used in surgery. The larger the calibre of the tubes the better, and it will be noticed that in this apparatus all tubes have been kept as large as possible. Nevertheless there is a limit beyond which it is not practicable to go, but this limitation only renders the apparatus very slightly less valuable, since the occasions upon which such materials have to be dealt with are few and far between. To give an example of the type of case the author recently attempted to use suction to empty a psoas abscess without success. By no means could the pus be drawn through the tube, although pressures approximating to atmospheric were applied. When the abscess was opened, however, it was found to be full of a thick caseous material of semi-solid consistency containing even more solid masses.

It has already been mentioned that old laminated clot cannot be removed by suction, but, on the other hand, recent clot which is likely to form during an operation can be removed with ease. There are, however, certain precautions to be taken. If continuous suction is kept up, and this is rarely advisable, no trouble arises, since the blood is kept moving along the tube and does not adhere to the walls. Where the usual periodical suction is used, however, the tube should always be dipped in lotion or a little saline poured into the wound before suction ceases. This washes the tube through and prevents occlusion from the formation of clot in the lumen. The small vent hole in the handle of the sucker will be found of great value where there is any tendency for the tube to become blocked, for if the hole be alternately closed and opened an intermittent suction is applied to the contents which is often successful when continuous suction fails; it will frequently, for instance, break up freshly clotted blood and detach it from the walls. Occasionally it will be noticed that the fluid in the collecting bottle tends to froth. If this becomes excessive it can be remedied by a little liquid paraffin. It has already been stated that the collecting bottle need not be sterilised, but if this precaution be taken fluids can be collected for bacteriological examination.

The apparatus can be used in conjunction with the bronchoscope or œsophagoscope for the removal of blood and secretions, and also more directly for the actual removal of certain types of foreign body, a specially shaped tube being applied to the object which is held in position by suction while the tube is removed. Finally, the author has found this pump indispensable in emptying the stomach completely of its contents as a preliminary to gastroscopic examination.

Since writing the above it has been brought to my notice that the Michelin Tyre Co. supply cylinders of air compressed to 1800 lb. to the square inch, at a little more than half the cost of a similar sized cylinder of oxygen.

The instrument is made by the Genito-Urinary Manufacturing Company, Ltd., of 64, Great Portland-street, W. 1, and I am indebted to their Mr. Schranz for the extreme care and accuracy with which he has carried out my ideas.

INTUBATION OF THE COMMON BILE-DUCT FOR STRICTURE.

By V. ZACHARY COPE, M.D., M.S. Lond., F.R.C.S. Eng.,
SURGEON TO OUT-PATIENTS, ST. MARY'S HOSPITAL; SENIOR SURGEON, BOLINGBROKE HOSPITAL.

One of the most difficult positions in which the surgeon can be placed is that of having to deal with a stricture of the common bile-duct after he has removed the gall-bladder, for the one definite use to which the gall-bladder can be put is to serve as a channel for the bile to reach the intestine by means of an artificial anastomosis made by the surgeon. Usually the operator is wise enough not to remove the gall-bladder until he has made sure that he has taken away the obstruction, but cases occur in which with all care the unfortunate condition of biliary obstruction may remain or develop after the viscus has been ablated. We assume that the obstruction is not due to a removable cause such as stone.

Chronic pancreatitis and growth of the head of the pancreas may arise at any period after the gall-bladder has been removed, and it is particularly to this class of case that the method I wish to describe is applicable. It is possible, of course, to divide the common bile-duct and anastomose it to the duodenum, or to make a lateral anastomosis between the bile-duct and the intestine; the technique for this has been well described by Walton. It must be admitted, however, that any operative method which includes the opening of the duodenum and the making of an artificial duct adds considerably to the risk in a patient who already may be sufficiently weak.

In a case which presented this problem I lately had recourse to an expedient which I have never known to be practised previously, and which has certainly had a wonderful immediate effect, and might well have a beneficial influence in other cases of a similar nature. Briefly, I dilated up the strictured portion of the duct by means of a Lister's bougie, and then intubated the stricture with a rubber drainage-tube which was left in the duct. The particulars of the case are as follows:—

Mrs. A., aged 66, began to have an irritation of the skin in June; on the 24th she vomited some acid material, and on the 30th she consulted a doctor. There was slight jaundice. The jaundice gradually increased and the irritation became torturing. She could not sleep, and sometimes had "shudders" without feeling cold. There was no pain at any time, nor had there been any serious illness at any period of her life. A week later I saw her in consultation. There was then extreme jaundice and tormenting itching, and the skin bore clear evidence of scratching. There was no pain, and no abdominal tumour could be felt. Pressure in the right hypochondrium elicited slight tenderness. Liver not demonstrably enlarged. We agreed upon the diagnosis of growth of the head of the pancreas and advised operation with a view to anastomosing the gall-bladder to the intestine.

Operation.—On August 10th an operation was undertaken at the local hospital. The abdomen was opened by a right paramedian incision splitting the rectus. The liver was found enlarged, and the gall-bladder tensely distended, but not projecting beyond the liver-edge. There were omental adhesions to the gall-bladder, and the liver near the gall-bladder showed a cystic dilatation. The gall-bladder was aspirated, much thick yellow stuff came away, and two very large gall-stones were removed. The stones were so large that they bulged towards the common duct, and it was thought that the liver-cyst and the stones might have caused temporary obstruction of the duct. No thickening or enlargement of the head of the pancreas was detected, though special search was made, nor was any stone found in the common duct or cystic duct. Cholecystectomy was performed. In separating the viscus from the liver an adhesion was broken and a copious flow of glairy material emptied the cyst. A tube was inserted into the beginning of the cystic duct and the abdomen closed.

Progress was satisfactory for a time. On August 27th all but an ounce of bile daily was passing by the normal channels; the jaundice disappeared, and the stools regained their normal colour. A week or two later, however, the jaundice reappeared, and the bile again began to discharge through the abdominal wound. This condition became worse, so I advised further exploration.

On Oct. 9th I reopened the abdomen and found to my dismay that there was a hard mass the size of a walnut projecting forward from the head of the pancreas. I explored the common duct and found no stone. In exploring the duct the idea occurred to me that it might be possible to dilate the stricture of the duct. I therefore passed a probe through the narrowed portion with some difficulty, and succeeded in dilating the stricture with a series of Lister's bougies. Knowing that the duct would soon contract again I then inserted with difficulty a small rubber tube so that it was tightly fixed in the stricture. Drainage down to the common duct completed the operation.

For 14 days after the operation the bile continued to come away through the abdominal wound, but then the wound completely healed and the stools regained their normal colour, and the patient left hospital looking and feeling well on Nov. 15th.

The patient has thus experienced the great benefit of being relieved of the jaundice.

FIBROCYSTIC DISEASE OF BONE.

NOTES ON THE PATHOLOGY OF TWO CASES.

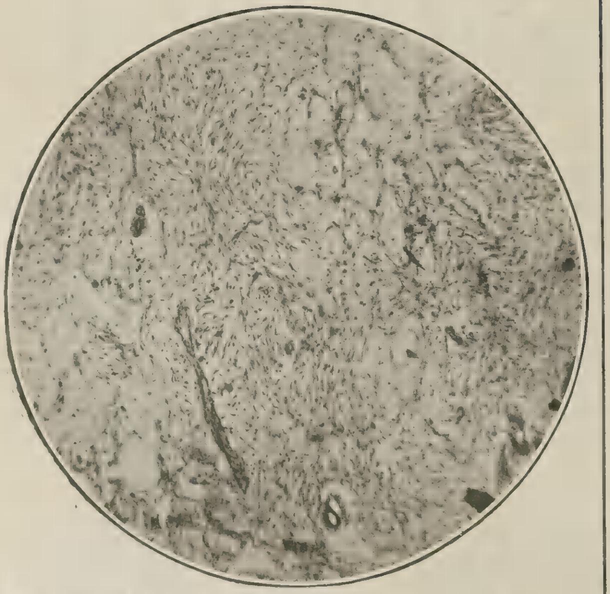
By J. B. G. MUIR, M.B., B.S. Lond., F.R.C.S. Eng.,
SURGICAL REGISTRAR, MIDDLESEX HOSPITAL.

The pathological origin of cystic cavities occurring in the medulla of long bones has for some time been a matter of contention. Apart from the rare cases of hydatid disease of bone, the majority of cysts have been ascribed to degenerative changes taking place in myelomata; that a solitary cyst in bone can be formed primarily is doubtful. In most of the published cases it seems probable that they are secondary formations.

An interesting group of cases, both from the pathological and clinical standpoint, are those in which one or several cysts occur in pre-formed fibrous tissue, replacing the true compact bone. Von Recklinghausen was the first investigator to classify and name this group, "osteitis fibrosa cystica," and Elmslie collected and published a series of such cases. Lawford Knaggs, in his Hunterian lecture of January, 1923, gave the following clinical classification: (1) cases in which the prime change is the development in the bone of a uniform mass of fibrous tissue; (2) cases in which such a uniform mass is showing signs of degenerating into cysts; (3) those in which much bone is developed, and the disease appears to be coming to an end; (4) single cysts of bone.

I quote this because the two cases about to be described fall exactly under the first two heads, illustrating an early and late stage of this condition. Both cases occurred in girls aged 14 years, and in both the right femur was affected, in one the upper and in the other the lower end.

Fig. 1.

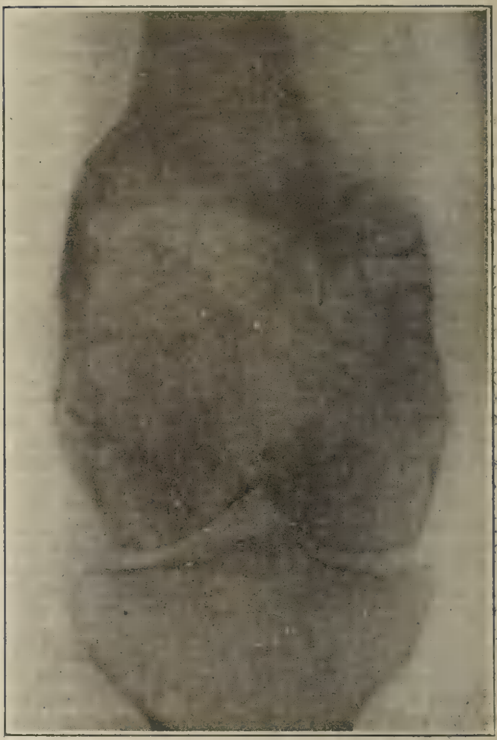


Case 1.—Showing material curetted from cystic cavity opposite the lesser trochanter of the right femur. Definite spindle-celled fibrous tissue can be seen, with inter-fibrillar spaces containing non-staining myxomatous tissue.

Case 1.—H. H., aged 14, fell on the right hip in March, 1920, and about three weeks later complained of pain over the great trochanter. She was admitted to the West Hants Hospital, Bournemouth, and as there was some limitation of movement, was considered to be an early case of tuberculous arthritis, and treated as such with benefit, the pain and limitation of movement disappearing.

A year later, however, she was readmitted with similar symptoms, and an enlargement of the subtrochanteric region of the right femur noted. An X ray showed this to be a cystic cavity. This was explored, the medulla opened, and a quantity of vascular myxomatous tissue removed. The pathologist's report was "spindle-celled sarcoma undergoing myxomatous degeneration and necrosis, probably highly malignant" (Fig. 1). A further curettage of the cavity was performed in July, 1921, and the pathologist's report was "spindle-celled sarcoma undergoing myxomatous degeneration—erosion of bone seen in part of the section."

Fig. 2.



Case 2 (July, 1922).—Radiogram showing large cystic expansion of lower end of femur, with marked bony trabeculation suggestive of a myeloma.

In view of these reports she was admitted to Middlesex Hospital in August, 1921, under the late Mr. T. H. Kellock, for radium treatment. Strangely enough, Case 2 was in the same ward at that time and a diagnosis of "osteitis fibrosa cystica" made in each case. In this instance it was considered, in view of the diagnosis, that treatment had been sufficient, and the patient was sent home to be kept under observation.

Since then she has been perfectly well, the affected femur is normal, and she is in no way incapacitated.

Case 2.—E. R., aged 14, was treated at Middlesex Hospital in November, 1920, for a supracondylar fracture of the right femur. Skiagram showed no pathological bone change and good union was secured with ordinary extension apparatus.

In June, 1921, she was readmitted under the late Mr. Kellock, the right femur having been re-fractured in the same locality, this time whilst she was walking to work. There now appeared to be a globular swelling of the lower end of the femur, and an X ray showed a large cystic cavity expanding the bone and causing a secondary fracture. A diagnosis of "osteitis fibrosa cystica" was made, and the site of fracture explored. A greyish gelatiniform mass was found to be protruding from the femur, and on being scraped away a large medullary cavity was evident, through which the fracture had occurred. Several large bony trabeculæ were present. It was cleaned out with spirit and filled with decalcified "bone bobbin," the patient treated with extension as before, and discharged after six weeks with a walking calliper splint.

The pathological report on the material removed was as follows: "The general appearance of tissue is that of a myxoma. It consists mainly of irregular branching nuclei, often widely separated from one another by an almost homogeneous matrix. Blood-vessels are numerous, and there are large areas of hæmorrhage scattered throughout. Some polymorphonuclear leucocytes are present. The possibility of this tumour being a sarcoma in which mucoid degeneration has occurred must be borne in mind."

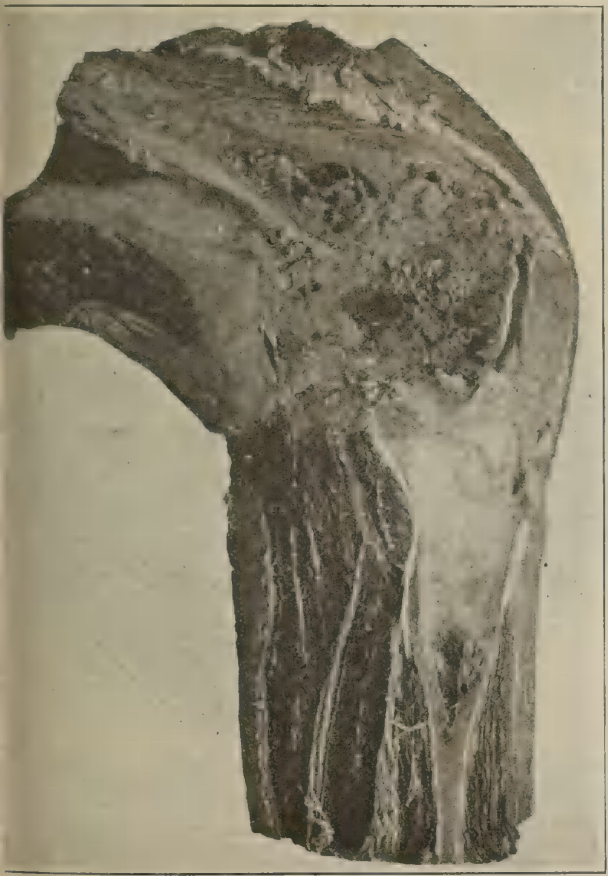
By July, 1922, the femur had again become very swollen (Fig. 2), and no weight could be borne on the limb. The patient was again admitted and curettage of the cavity performed, Morton's fluid being injected. Section of the curetted material showed numerous spindle-shaped nuclei separated by fine fibrils, and was diagnosed as a "fibrosarcoma." In December, 1923, the swelling of the femur had greatly increased, and as the limb was now shortened to the extent of 2½ inches, Mr. John Murray decided to amputate. This he performed through the middle third of the right femur, the shaft at site of section showing no pathological change. The patient made an uneventful convalescence, and has since then been perfectly well.

Pathological Considerations.

Macroscopic.—The amputated limb was frozen and sawn sagittally through the knee-joint (Fig. 3). A fracture is present at the supracondylar region of the femur, a fairly compact shaft fragment being impacted into a spongy and cystic condylar portion. Occupying the last inch of the entire medullary cavity is a large multilocular cyst. The lower portion consists of a spongy fibrous matrix, with a tendency to lamination in places. There are numerous small cystic spaces and several areas where hæmorrhage has occurred. The knee-joint is intact, although cartilage erosion appears to have begun at one place.

Microscopic.—Sections taken from portions of the affected area show: (1) At the edge—definite invasion of bone under the epiphyseal cartilage by a delicate connective-tissue reticulum with scanty spindle-shaped nuclei. (2) Centrally the reticulum becomes definitely fibrous with many scattered and elongated spindle-shaped cells, and cystic spaces are present. They are empty and possess no lining membrane. The larger ones appear to have been formed by the breaking down of the intralocular septa. Fibrous tissue bundles are especially prominent in places, and, cut transversely, give an almost small round-celled appearance.

FIG. 3.



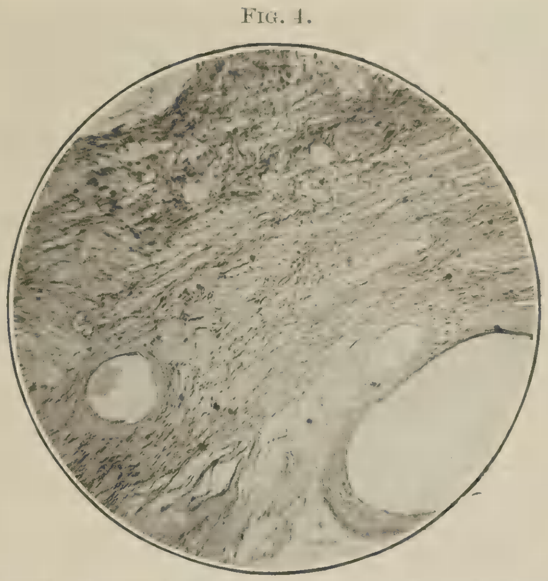
CASE 2 (December, 1923).—Amputated limb sawn sagittally. The tibia is quite normal, but the markedly cystic and spongy nature of the lower end of the femur can be seen.

There is an entire absence of fat and of any giant cells of the myeloma type.

Summary.

Thus two similar pathological conditions were occurring in each case, in the one in the upper and subtrochanteric region of the femur, and in the other in the lower or supracondylar region. Two independent pathologists of repute suggested the possibility of a spindle-celled sarcoma undergoing malignant degeneration in each case, and this very naturally, as a myxofibroma occurring endosteally is a practically unheard-of phenomenon. The pathological condition, however, seems clear. The preliminary change is the appearance of fibrous tissue in the marrow, which becomes entirely replaced. Later, an invasion and absorption of the compact bone occurs.

FIG. 4.



CASE 2.—Showing laminated fibrous tissue with cystic spaces.

A later development is the formation of cystic spaces within the fibrous tissue, the coalescence of these leading to larger cysts (Fig. 4). Such a condition, if it extends, will inevitably lead to secondary fracture. The preliminary treatment in each case was the curetting away of all affected tissue, and this, if done sufficiently early and thoroughly, would seem to be sufficient (vide Case 1). Should the condition progress, however, amputation appears to be the only available line of treatment, as in Case 2.

Why such a replacement of compact bone by fibrous tissue should occur is hard to say. In neither of these cases was there any evidence of inflammatory change. Knaggs believes that the condition arises in response to toxic influences which select a site that is in some way devitalised. That the disease may affect most of the bones of the skeleton is recognised, just as in osteitis deformans; and illustrative cases have been published by Von Recklinghausen and Fugii, and this has been advanced as an argument in favour of a general bony change, induced by toxic elements. At the same time there seems to be no great argument against the fact that the condition may arise primarily as a myxofibroma of bone, and that in rare cases, just as in "multiple myelomatosis," several bones may be affected.

I am indebted to Mr. John Murray for permission to publish Case 2, and to Dr. Knyvett Gordon for the loan of section of Case 1.

A CASE OF OSTEITIS FIBROSA.

BY H. W. SOUTHGATE, M.B., B.S., B.SC. LOND.,
LECTURER ON PHARMACOLOGY; FORMERLY DEMONSTRATOR OF PATHOLOGY, UNIVERSITY OF SHEFFIELD.

THE following notes with illustrations of a case showing the typical pathological changes described by Paget,[1] but associated with fragility of the bones and bone tumours, are worth recording, owing to the relatively rare incidence of the condition.

H. W., a married woman, aged 40, was admitted into the Sheffield Royal Hospital, under Prof. Arthur J. Hall, complaining of general weakness and pain in the sides, back, and head.

Previous History.—She complained of having suffered from "rheumatism" for years. Five years previously the patient had a growth removed from the lower jaw in Ripon Hospital, and was discharged as cured. She has had no children or miscarriages.

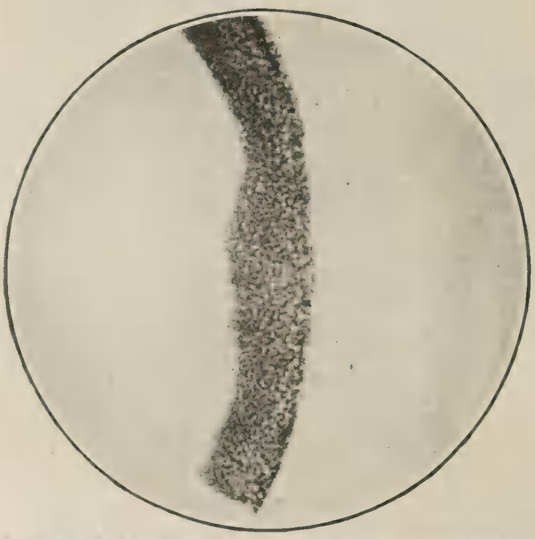
History of Present Illness.—Three years previous to admission she had noticed the development of general weakness with increasing inability to move about. Her periods became irregular, and she had some attacks of severe flooding. On admission she complained of pain in her joints. She looked emaciated and pale, and had palpitation on the least exertion. The heart was enlarged, and there was an apical systolic murmur conducted into the axilla. The brachial and radial and the arteries of the leg showed extreme thickening, so that the pulse (about 85) was difficult to take at the wrist.

Osseous System.—There was marked bending forwards of the whole sternum, forming an arc with convexity forwards. There was slight kyphosis in the lower thoracic region. There was no noticeable bowing of the limbs. No undue fragility of the bones was observed during life, and there had been no history of fracture.

The urine contained a large quantity of albumin.

Progress.—The symptoms and signs of chronic granular nephritis were so marked and the arterio-sclerosis so extreme that there seemed no reason to look for anything further. Ten days before her death she had a fit and became unconscious. There was frothing at the mouth, but no twitching or convulsion. The third day following this attack she became acutely maniacal with some vomiting. There was no pyrexia. Next day the maniacal symptoms had disappeared, but the vomiting continued. This was followed by a return to the maniacal condition with commencing gangrene of the finger-tips. Two days later, on the day before her death, the toes were similarly affected.

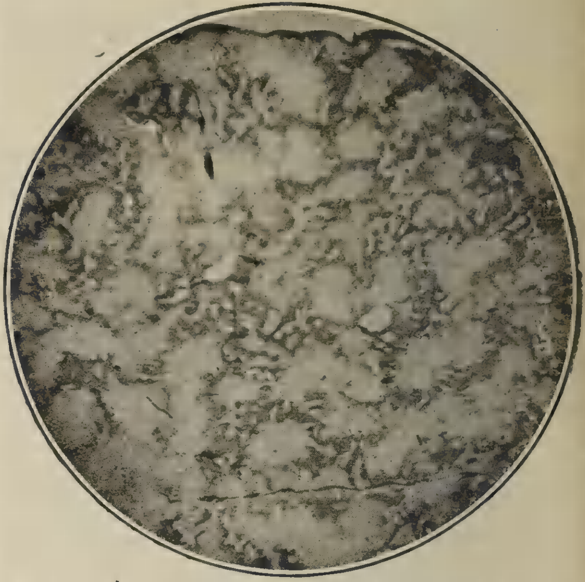
FIG. 1.



Radiogram of thin slice of skull vault, showing replacement of normal by irregular areas of calcified and uncalcified tissue.

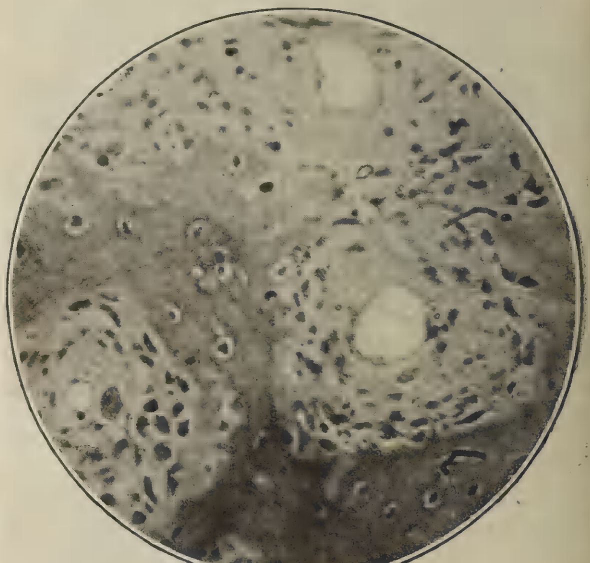
Post-mortem Examination.—An abnormal bone condition was discovered on removing the skull-cap. The screws of the "P.M. helmet" were found to penetrate the bone very easily. The vault wall was, in fact, cut with a knife with a sensation of cutting something soft containing grit. The skull wall was found to be irregularly increased in thickness, varying from 8 to 18 mm. All distinction of diploë had disappeared and the cut surface presented a speckled appearance with minute translucent areas studded through the bone (Fig. 1). On attempting to cut through the rib cartilages it was found that the ribs themselves were quite fragile and could easily be broken with the fingers. On the eighth left rib a large swelling was seen close to the neck (Fig. 4). Two other ribs had each a much smaller swelling. The vertebræ could be cut through quite easily with the knife. On raising the right leg during the post-mortem examination the femur broke across. The coronary arteries were sclerosed and the muscular tissue of the heart was soft and friable. In the aorta there were only slight atheromatous changes,

FIG. 2.



Transverse section of skull vault. The dark areas represent calcified parts; in the lighter, the cells are of the interstitial spindle-cell type.

FIG. 3.



Higher magnification of part of Fig. 2, showing the darker calcified area and the vascular nature of the uncalcified tissue.

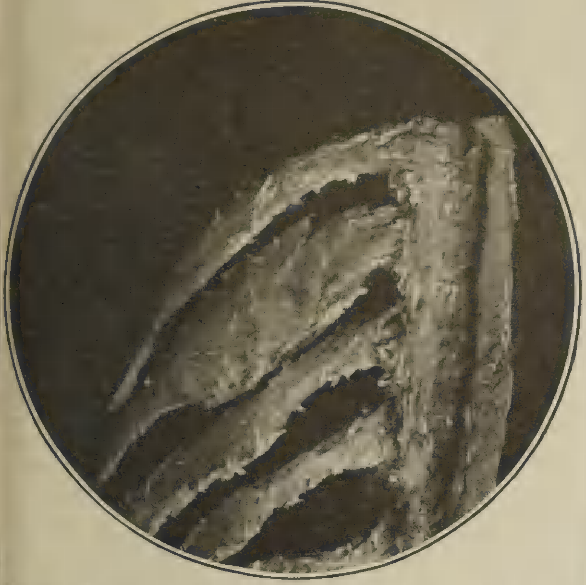
but the more distal arteries of the limbs were extremely narrowed and calcareous. The splenic artery was also sclerosed and calcareous. The kidneys were very small and showed extreme cirrhosis; the arteries here were much thickened. The calyces contained numerous small calculi.

FIG. 4.

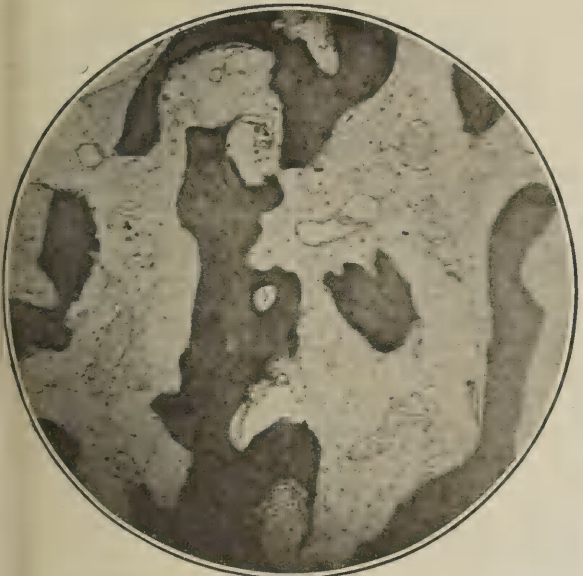


Showing tumour on the eighth rib, a fusiform swelling with a maximum circumference of about 4½" at the level of the angle of the rib.

Review of the Case.

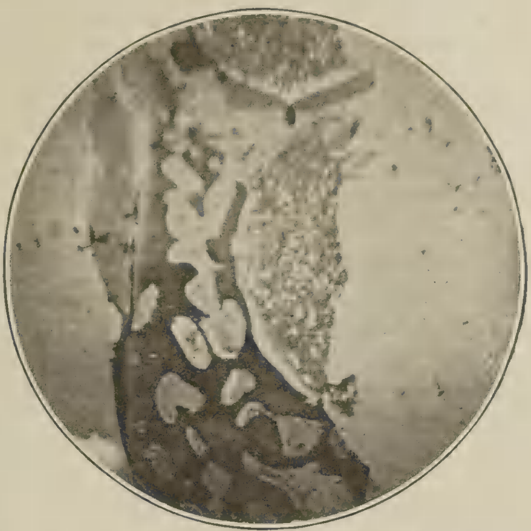
Reviewing, then, the main facts of the case, the definite irregular enlargement of the skull vault with haphazard calcification and absorption, a history of ntermittent pains ("rheumatism"), the bone tumours, and the extreme atheromatous condition of the smaller vessels—they all point to Paget's disease. The wasting condition in the ribs and other bones, where the cortex is being irregularly replaced by a delicate vascular fibrous tissue (thus making these bones extremely fragile), suggests, however, that the case might perhaps be more correctly classed among those associated with the name of von Recklinghausen—at least, the post-mortem findings and histological changes are very similar to those described by him under Osteitis Fibrosa, in Section 1B, Case 7, of Virchow's "Festschrift."[2]

FIG. 5.



Section of the growth shown in Fig. 4. Shows dark calcified lamellæ separated by irregular delicate but highly vascular fibrous tissue. The growth appears to be benign.

FIG. 6.



Shows the process in the ribs; the cortex undergoing absorption to be replaced by delicate vascular fibrous tissue. Marrow cavity not yet encroached upon.

In conclusion, I would express my thanks to Prof. Hall for his kindness in allowing me to publish the notes of this case, and for his criticisms and help.

INHERITED SYPHILIS AND TUBERCULOSIS.

BY W. T. MUNRO, M.D., D.P.H. ST. AND.,
MEDICAL SUPERINTENDENT, FIFE AND KINROSS
(GLENLOMOND) SANATORIUM.

THE following paper comprises the results obtained and views formed from an investigation into the incidence of inherited syphilis among 100 children admitted to Fife and Kinross Sanatorium. In this investigation a routine serological examination was made in 100 children, medical and surgical, as they were admitted. It was hoped to determine (1) the incidence of inherited syphilis among 100 tuberculous children; (2) how far syphilis predisposes to the superadded infection with tubercle bacilli (T.B.); and (3) how far the conditions could be modified by anti-syphilitic remedies.

One was careful to obtain indisputable evidence of the existence of both infections. In all cases of pulmonary lesions careful methods for the discovery of the T.B. in sputum were resorted to, and an effort was made to obtain cultures. Where T.B. could not be found and could not be grown the skin sensitiveness was taken as evidence of infection. In this connexion it is well to note that inherited syphilis does not of itself give a positive skin reaction to tuberculin.[1] In the surgical cases, any abscess or exudate was carefully examined for T.B., and if none were found a guinea-pig was inoculated; where no abscess or exudate existed skin sensitiveness was again resorted to.

---

[2] Festschrift Rudolph Virchow, zu seinem 71 Geburtstage, Berlin, 1891.

With regard to infection by the spirochæte, while a positive Wassermann reaction (W.R.) was strongly suggestive the various stigmata were always looked for. Some of the cases exhibited excellent examples of late luetic lesions, such as interstitial keratitis, atrophic rhinitis, and the various dental anomalies. In only one case was there failure to discover any lesion suggestive of inherited syphilis when the W.R. was positive, but Gougerot[2] points out that hereditary syphilis can exist without stigmata. According to Harrison,[3] 95 per cent. of inherited syphilitics give a positive W.R., while 5 per cent. may fail to give it. The W.R. wanes as the child gets older, and Dean[4] surmised that a series of young children would probably give a fairly high percentage of positive results.

Literature.

A comprehensive review of the literature which has arisen around these dual infections is to be found in the *Archives of Dermatology and Syphilology*, August, 1921, Hollander and Narr. In a paper by these two authors there is a detailed percentage of positive Wassermann reactors found among the tuberculous by various workers. Some of the figures correspond very closely to our examination of 100 adults.* Thus Letulle, Bergeron, and Lépine find 19 per cent. positive, Vedder 23 per cent., and Petroff 22 per cent. A similar investigation so far as children are concerned does not seem to have been made. Hochsinger[5] is of opinion that children with hereditary syphilis offer a favourable ground for the reception and development of tuberculosis. Fournier[6] remarks that tuberculosis so often develops on a basis of syphilis that inherited syphilis should be suspected in masked cases. Again, D'Arcy Power[7] says children with hereditary syphilis often show signs of tuberculous disease of joints. Gougerot[8] writes on hereditary syphilis that there are often enlarged glands associated with the bacillus of Koch. Emile Sargeant[9] writes that tuberculosis awaits the inherited syphilitic. Hutinel and Merklen[10] found evidence of congenital syphilis in 11 per cent. of 206 cases of tuberculous meningitis. They consider that the meninges are damaged by syphilis and thereby predisposed to tuberculous infection. In South Africa Brock,[11] in an inquiry as to the incidence of syphilis among natives, writes that syphilis prepares the way for tuberculosis, that it plays a rôle in the production of lung disease in youth and adult, the importance of which has not been recognised.

1. *Incidence.*

If it is true that inherited syphilis plays a part in the production of tuberculosis, then one would expect the incidence of inherited syphilis to be higher among tuberculous children than among a general "child" population of the same age and social status. Fortunately figures are available. Quoting from Leonard Findlay[12] Browning put the incidence of inherited syphilis among a general child population at 10 per cent. Elliot,[13] in a series of 130 children, found the incidence to be 10·8 per cent., but he thought 8 per cent. would be a truer indication, as he felt he had included an unusual number of typically congenital syphilitics. Churchill and Austin[14] found among 695 children in Chicago that 3·3 per cent. presented clinical evidences of syphilis. Among 100 children examined at Glenlomond the incidence of inherited syphilis works out at 11 per cent. There has been no selection of cases, and each child has had a W.R. done in the first week of admission.
